ARTICLE INFO

ABSTRACT

Editorial handling by Jon Petter Gustafsson

Keywords: FeS Antimony Interaction Phosphate Impact

Phosphate may affect the behavior of metal(loid)s in environments, so the interaction of Sb(III) with FeS affected by phosphate was investigated in this study. Sb(III) was reacted with synthesized FeS in solution at pH 5.5, 7.0, and 9.0 with and without the addition of phosphate. The concentrations of Fe(II), Sb(III), and phosphate in the solution were monitored, and the solid phases were examined by XRD, TEM, and XPS. For the interaction of Sb (III) with FeS in the absence of phosphate, the formation of Sb_2S_3 was very important at pH 5.5 and 7.0, whereas Sb(III) adsorption was the dominant process at pH 9.0. The interaction of Sb(III) with FeS could be significantly affected by phosphate, and this impact was dependent of pH and phosphate concentration. At pH 5.5 and 7.0, the effect of phosphate varied markedly with increasing phosphate concentration. Low phosphate loadings (9.5 and 19 mg/L) had a negligible effect on the mobility of Sb(III), while high phosphate loadings (95 and 475 mg/L) notably enhanced the uptake of Sb(III) by FeS. In the case of high phosphate loadings, $Fe_3(PO_4)_2·8H_2O$ was formed and resulted in the dissolution of FeS, which was favorable for the formation of Sb_2S_3 and consequently the uptake of Sb(III). In the experiments at pH 9.0, the addition of phosphate only resulted in minor desorption of Sb(III) because FeS was very stable and consequently both $Fe_3(PO_4)_2·8H_2O$ and Sb_2S_3 were unlikely to be formed. The results of this work may help to better understand the effect of phosphate on the behavior of Sb in some anoxic environments where FeS is present.

1. Introduction

Antimony is a toxic and carcinogenic metalloid of global concern ([Amarasiriwardena and Wu, 2011](#page-6-0); [Kulp et al., 2014](#page-7-0)). It has been recognized as a pollutant of priority interest by the European Union and the United States Environmental Protection Agency ([Ungureanu et al.,](#page-7-0) [2015\)](#page-7-0). The release of Sb into the environment can occur as a result of human activities related to mining and some industrial processes such as mining/smelting and the manufacture of alloys, semiconductors, fire retardants, glass, and polyethylene terephthalate [\(Filella et al., 2002a](#page-7-0); [He et al., 2012\)](#page-7-0). In environmental systems, Sb can be present in four oxidation states $(-3, 0, +3, \text{and } +5)$ but is mostly found in two oxidation states ($+3$ and $+5$). It usually occurs as $Sb(OH)_6$ ⁻ (Sb(V)) in relatively oxic environments or Sb(OH)₃ (Sb(III)) in anoxic environments (Filella [et al., 2002a](#page-7-0), [2002b;](#page-7-0) [Wilson et al., 2010](#page-7-0)). In sulfidic systems, Sb can react with sulfide and lead to the formation of thioantimonite complexes such as $HSp_2S_4^-$ or $Sp_2S_4^-$ [\(Spycher and Reed, 1989](#page-7-0); [Polack et al., 2009](#page-7-0);

[Hockmann et al., 2020](#page-7-0)).

The mobility of metal(loid)s in the environment has been recognized to be highly related to minerals. In terrestrial environments, ubiquitous Fe(III) hydro(oxides) such as ferrihydrite, goethite, and hematite are recognized as the primary host phases for metal(loid)s. In anoxic environments, however, reductive transformation of Fe(III) hydro(oxides) occurs due to microorganisms or reducing agents and metal(loid)s are subsequently released and redistributed ([Li et al., 2006;](#page-7-0) [Kocar et al.,](#page-7-0) [2010;](#page-7-0) [Burton et al., 2011\)](#page-7-0). Meanwhile, sulfate-reducing bacteria in anoxic environments can reduce sulfate to sulfide that subsequently reacts with ferrous ion ([Watson et al., 1995](#page-7-0); [Jong and Parry, 2003](#page-7-0)). Amorphous FeS is typically the initial iron sulfide phase to be formed post to the reduction of Fe(III) hydro(oxides). It is generally considered a nanocrystalline form of mackinawite [\(Wolthers et al., 2003](#page-8-0); [Burton](#page-7-0) [et al., 2011,](#page-7-0) [2019\)](#page-7-0). The newly formed FeS can serve as a major sink of metal(loid)s that are released from the reductive transformation of Fe (III) hydro(oxides). For example, As(III) and Sb(III) have been recognized to be significantly sequestered by FeS in anoxic environments ([Han et al., 2011](#page-7-0), [2018\)](#page-7-0). As a consequence, FeS can significantly affect the mobility of metal(loid)s in sediment or groundwater [\(Wolthers](#page-8-0) [et al., 2003, 2005](#page-8-0); [Han et al., 2011](#page-7-0)).

Increased inputs of nutrients into rivers, lakes, and estuaries can affect the mobility of metal(loid)s in supergene environments ([Park](#page-7-0) [et al., 2018](#page-7-0); [Neidhardt et al., 2021](#page-7-0)). For example, dissolved As can entirely adsorb to aquifer sediments in the absence of PO_4^3 ⁻, whereas strong competition between PO_4^{3-} and dissolved inorganic As in the form of $AsO₃³⁻$ and $AsO₄³⁻$ can be assumed when $PO₄³⁻$ is present ([Biswas et al., 2014](#page-7-0); [von Bromssen et al., 2008\)](#page-7-0). Competition of $PO₄³$ and As for sorption sites was observed by [Rathi et al. \(2017\)](#page-7-0) in laboratory sorption experiments using orange-colored aquifer sediment. As a result of the competition between PO $_4^{3-}$ and As, remarkably high PO $_4^{3-}$ and As concentrations were observed in anoxic groundwater of floodplain aquifers in large Asian deltas such as the Bengal Delta or the Red River Delta ([Neidhardt et al., 2018;](#page-7-0) [Podgorski and Berg, 2020\)](#page-7-0).

In the interaction with FeS under anoxic conditions, As(III) or Sb(III) can react strongly with FeS. Previous studies reported the formation of As(III)–S complex or As_2S_3 [\(Wolthers et al., 2005;](#page-8-0) [Han et al., 2011, 2018](#page-7-0); [Burton et al., 2014](#page-7-0)), AsS ([Han et al., 2011\)](#page-7-0), Sb(III)–S complex or Sb_2S_3 ([Han et al., 2018](#page-7-0); [Li et al., 2021](#page-7-0)) or $SbS₃$ -like precipitates (Kirsch et al., [2008\)](#page-7-0) on the surface of FeS. The interaction between metal(loid)s and FeS particles may become more complicated in the presence of PO_4^3 ⁻. Particularly, co-existence of Fe₃(PO₄)₂·8H₂O and FeS was observed in the biotic transformation of schwertmannite coupled with PO_4^3 ⁻ addition [\(Schoepfer et al., 2019](#page-7-0)) and at the sediment-water interface of an urban canal [\(Dodd et al., 2003\)](#page-7-0). Moreover, in the application of phosphate to the mitigation of metal(loid) mobility [\(Munksgaard and Lot](#page-7-0)[termoser, 2013;](#page-7-0) [Saavedra-Mella et al., 2019](#page-7-0)) in some sulfidic mine tailings, high concentrations of PO_4^{3-} and Sb can be present in anoxic layers where reduction of abundant sulfate and Fe(III) to H_2S and Fe(II) can also occur. The crystalline precipitate of $Fe₃(PO₄)₂·8H₂O$ is called vivanite, which is an authigenic mineral that is commonly found in aquatic systems, terrestrial systems as well as wastewater sludges ([Rothe](#page-7-0) [et al., 2016\)](#page-7-0). As to the effect of PO_4^{3-} on the interaction of As(III) with FeS, [Niazi and Burton \(2016\)](#page-7-0) reported that PO_4^{3-} had a negligible effect on the sorption of As(III) on FeS in the pH range of 6–9. [Park et al. \(2018\)](#page-7-0) added oxidized and fresh FeS into metal(loid)-contaminated soil and investigated the mobility of As and Sb under oxic and anoxic conditions, and concluded that the presence of PO_4^{3-} apparently inhibited the sorption of As but did not significantly change Sb sorption. We hypothesized that the interaction of Sb(III) with FeS may be affect by PO_4^{3-} via the formation of Fe₃(PO₄)₂·8H₂O. To examine this hypothesis, we reacted aqueous Sb(III) with synthesized FeS under anoxic conditions (in the absence and presence of PO $_4^{3-}$) and monitored the mobility of Sb in this system, so as to better understand the mobility of Sb in anoxic environments that received high inputs of PO_4^3 ⁻.

2. Materials and methods

2.1. Materials

Deionized water (DW) (resistivity: 18.2 MΩ cm) was prepared with a Milli-Q system (Millipore, Bedford, MA, USA). Deoxygenated deionized water (DDW) was prepared by sparging DW with high-purity N_2 (99.99%). Potassium antimonyl tartrate (PAT) sesquihydrate (*>*99% purity) was purchased from Acros Organics Inc. (New Jersey, USA). Ferrous sulfate heptahydrate (FeSO₄·7H₂O), sodium sulfide nonahydrate (Na₂S⋅9H₂O), anhydrous dibasic sodium phosphate (Na₂HPO₄), and other chemicals were of analytical grade. All solutions were prepared with DDW. Stock solutions of Sb(III) (500 mg/L), S(–II) (6.4 g/L, 0.2 M), and Fe(II) (11.2 g/L, 0.2 M) were prepared by dissolving potassium antimonyl tartrate sesquihydrate, sodium sulfide nonahydrate, and ferrous sulfate heptahydrate in DDW, respectively.

possible complexation of Sb(III) by tartrate ([Filella and Williams, 2010](#page-7-0); [Filella and Williams, 2012](#page-7-0)). However, [Li et al. \(2019\)](#page-7-0) reported that the effect of 0.5 mM tartrate on the adsorption of Sb(III) on granular ferric hydroxide was likely minor. Moreover, the high solubility of PAT allowed the use of high Sb(III) concentrations (20 mg/L) in our experiments, while the solubility of another frequently used Sb(III) reagent - $Sb₂O₃$ was reported to be only 12.6 mg (Sb)/L (Gayer and Garrett, [1952\)](#page-7-0).

2.2. Synthesis of FeS and experiments

The synthesis of FeS and the interaction of Sb(III) with FeS in the absence and presence of PO_4^{3-} were conducted in an anaerobic chamber (Model 855-ACB, PLAS-LABS, CO, USA) at an atmospheric composition of 95% Ar/5% H2. The residual oxygen inside the chamber was removed by Pd catalysts, resulting in an oxygen concentration below 1 ppm.

For the synthesis of FeS, a method proposed by [Jeong et al. \(2008\)](#page-7-0) was applied. In brief, 0.2 M FeSO₄ solution and 0.2 M Na₂S solution (V:V $= 1:1$) were mixed and black FeS precipitates were quickly formed. The characteristics of FeS synthesized by the reaction of Fe(II) with S(–II) were previously reported by [Ma et al. \(2020\)](#page-7-0) and [Li et al. \(2021\).](#page-7-0) The XRD pattern of the FeS precipitates is shown in Fig. 1. Overall, the synthesized FeS was amorphous and appeared as clusters of very fine grains because FeS particles tended to agglomerate rapidly.

The freshly precipitated FeS was aged for 3 h before it was used for the experiments on the interaction of Sb(III) with FeS. Sodium chloride was added to obtain 0.1 M (5.85 g/L) NaCl as a background ionic medium. Then, stock solutions of Sb(III) and PO_4^3 ⁻ were added into the FeS suspension to obtain preset initial Sb(III) and PO_4^3 ⁻ concentrations. The pH of the initial suspension was adjusted by the addition of 0.1 M HCl and 0.1 M NaOH. The initial volume of the solution was adjusted to 50 mL through the addition of DDW. The reaction mixture was sampled at the end of experiments. After collection, the solution sample was immediately filtered using a cellulose membrane (0.22 μm pore size) for determination of the pH and the concentrations of dissolved Sb(III), Fe (II), and PO_4^3 ⁻. The final solid phases of the experiments were separated and immediately dried using a vacuum freeze drier.

Batch experiments on the interaction of Sb(III) with FeS in the absence and presence of PO_4^{3-} were carried out. For all experiments, the initial concentrations of FeS and Sb(III) were preset to 44 mg/L and 20 mg/L, respectively. After mixing of FeS particles and Sb(III) solution, $PO₄^{3–}$ solution was added. In the experiments in the presence of $PO₄^{3–}$,

Fig. 1. The XRD patterns of the synthesized FeS and the solid phases of experiments P-0 and P-95.

the initial concentration of PO $_4^{3-}$ was preset at low loadings (9.5 and 19 mg/L) and high loadings (95 and 475 mg/L). Experiments were conducted in polyethylene vials. The vials were removed from the anaerobic chamber and placed on a shaker to mix the suspensions thoroughly. The reaction time was 24 h. All experiments were carried out at room temperature (20–25 ◦C) in triplicate. Other details for each experiment were later given in the caption of the figures.

2.3. Analyses and solid characterization

The pH of the solution was measured with a Denver UB-7 pH-meter. The concentration of Fe(II) was measured by a 1,10-phenanthroline spectrophotometric method [\(APHA, 1998\)](#page-6-0). The precision of the measurement of Fe(II) in the solution was better than 3%. Dissolved sulfide was measured immediately using the methylene blue method [\(Green](#page-7-0)[berg et al., 1992](#page-7-0)) (detection limit: 0.2 mg/L). The concentration of PO_4^{3-} was determined by an ammonium molybdate spectrometric method [\(Liu et al., 2021](#page-7-0)), and the concentration of Sb(III) was determined by hydride generation-atomic fluorescence spectrometry (HG-AFS) (AFS-2202E, Haiguang Instruments Corp., Beijing, China) following a method from [Fu et al. \(2016\).](#page-7-0) The limit of detection for Sb (III) based on 11 replicate analyses was 0.05 μg/L, and the relative standard deviation was 0.6%.

The mineralogy of the synthesized FeS and the solid phases after interaction was characterized by X-ray diffractometer (Empyrean, PANanalytical Co., The Netherlands) using a Cu tube and a scanning range from 4◦ to 60◦ with a step size of 0.03◦ and 8 s/step measuring time. The solid phases after the interaction were also examined by a field emission transmission electron microscope equipped with an energy dispersive spectrometer (TEM-EDS, Tecnai G2 F20 S-TWIN, FEI Inc., USA) and X-ray photoelectron spectroscopy (XPS, ESCALAB 250Xi, Thermo Fisher Scientific, Inc, USA).

3. Results and discussion

3.1. The FeS + *Sb(III) system*

For the experiments at pH 5.5, 7.0, and 9.0, the concentrations of Sb $(III)_{aq}$ after the interaction of Sb(III) with FeS were 6.9, 9.6, and 13.8 mg/L, respectively (Fig. 2, experiment P-0). The lower $Sb(III)_{aq}$ concentration at lower pH indicated that the uptake of Sb(III) increased with decreasing pH. Meanwhile, the concentration of $Fe(II)_{aq}$ increased notably with decreasing pH (Fig. 2b, experiments P-0), indicating that the dissolution of FeS greatly increased with decreasing pH. Consistently, the higher dissolution of FeS at lower pH has also been previously reported ([Wolthers et al., 2005;](#page-8-0) [Han et al., 2018;](#page-7-0) [Li et al., 2021](#page-7-0)). In detail, the corresponding concentrations of solid FeS after interaction at pH 5.5, 7.0, and 9.0 were 15.3, 40.8, and 43.9 mg/L, respectively. Overall, the pH 5.5 experiments showed the highest uptake of Sb(III) while it had the least solid FeS, implying that an important mechanism have notably increased the uptake of Sb(III) at low pH.

For the experiments at pH 5.5 and 7.0, the TEM-EDS analysis of the solid phases showed strong signals of Sb and S [\(Fig. 3](#page-3-0)), so precipitation of Sb2S3 was suggested to be important for the uptake of Sb(III) by FeS under acidic and neutral conditions. This notion was in agreement with that of previous studies [\(Han et al., 2018](#page-7-0); [Li et al., 2021\)](#page-7-0). It should be noted that electrostatic adsorption and Sb(III)–S surface complexes could also contribute to the uptake of Sb(III). In previous studies, the formation of SbS_3 -like solid ([Kirsch et al., 2008](#page-7-0)) and surface complex Sb–S [\(Han et al., 2018\)](#page-7-0) has been proposed. For the pH 9.0 experiments, $Sb₂S₃$ was not been found in the solid phases. A typical result of the TEM-EDS examination of all the pH 9.0 samples is shown in Fig. S1. It was proposed that Sb(III) was primarily sequestered by FeS through adsorption. The adsorption of Sb(III) at pH 9.0 could be related to the species of Sb(OH)₃ and Sb(OH)₄. [Han et al. \(2020\)](#page-7-0) reported that As could be bound to FeS on the Fe(II) and S(–II) sites. Moreover, in a study

Fig. 2. Aqueous Sb(III), Fe(II), and PO₄³⁻ concentrations of the experiments (P-0, P-9.5, P-19, P-95, and P-475 represent the experiments in the presence of 0, 9.5, 19, 95, and 475 mg/L phosphate, respectively).

on the adsorption of As(III) on FeS particles, [Gallegos et al. \(2007\)](#page-7-0) suggested that more As(III) was bound on the Fe(II) sites with increasing pH whereas more As(III) was bound on the S(–II) sites with decreasing pH. Because Sb usually shows a similar chemical behavior to As ([Filella](#page-7-0) [et al., 2002a](#page-7-0)), it is proposed that Sb(III) was primarily bound on the S (–II) sites at pH 5.5 and 7.0 and bound on the Fe(II) sites at pH 9.0.

3.2. The FeS + *Sb(III)* + *PO4 ³*[−] *system*

The concentrations of Sb(III)aq and Fe(II)aq in the FeS $+$ Sb(III) $+$ $PO₄^{3–}$ experiments are also shown in Fig. 2 for comparison with the FeS

Fig. 3. Precipitates of Sb₂S₃ in the solid phases of experiments P-0 (a and b: TEM image and EDS spectrum of pH 5.5 sample; c and d: TEM image and EDS spectrum of pH 7.0 sample) (The signal of Cu, C, and O originated from the support grids for sample).

+ Sb(III) experiments. P-9.5 and P-19 represent the experiments with low PO $_4^{3-}$ loadings (9.5 and 19 mg/L), while P-95 and P-475 represent the experiments with high PO_4^{3-} loadings (95 and 475 mg/L).

For the FeS + Sb(III) + PO_4^{3-} experiments at pH 5.5 and 7.0, the effect of high PO_4^{3-} loadings differed significantly from that of low PO_4^{3-} loadings. The concentration of Sb(III)_{aq} did not vary when the concentration of PO_4^{3-} increased from 0 to 19 mg/L, but decreased significantly when the concentration of $PO_4^{\,3-}$ increased to 95 and 475 mg/L ([Fig. 2](#page-2-0)a). This indicated that, at pH 5.5 and 7.0, low PO_4^3 loadings had a negligible effect on the uptake of Sb(III) but high PO $_4^3$ loadings notably enhanced the uptake of Sb(III). Moreover, in the TEM-EDS examination of the solid phases, $Fe_3(PO_4)_2·8H_2O$ and Sb_2S_3 precipitates were found in experiments P-95 [\(Fig. 4\)](#page-4-0) and P-475 (Fig. S2), whereas only Sb_2S_3 precipitates were found in experiments P-9.5 and P-19. Overall, for the experiments with high PO_4^{3-} loadings, the occurrence of Fe₃(PO₄)₂·8H₂O in the solid phases and the notable decrease in the concentration of $Sb(III)_{aq}$ [\(Fig. 2a](#page-2-0)) probably indicated that high PO_4^{3-} loading resulted in the formation of $Fe_3(PO_4)_2·8H_2O$ and consequently enhanced the immobilization of Sb(III). The precipitates of $Fe₃(PO₄)₂·8H₂O$ and $Sb₂S₃$ were not discernible in the XRD analysis ([Fig. 1\)](#page-1-0), implying that they were amorphous or poorly crystalline. Consistent with the formation of $Fe₃(PO4)₂·8H₂O$, the concentration of Fe(II)aq in the pH 5.5 experiments notably decreased when the PO $_4^3$ loading increased to 95 and 475 mg/L [\(Fig. 2](#page-2-0)b). However, the concentration of Fe(II)aq in the pH 7.0 experiments gradually increased when PO_4^{3-} loading increased from 0 to 475 mg/L. This result can not be well explained. The precipitation of Sb_2S_3 and $Fe_3(PO4)_2·8H_2O$ is specifically discussed in section [3.4.](#page-4-0)

For the FeS + Sb(III) + PO_4^{3-} experiments at pH 9.0, Sb₂S₃ or $Fe₃(PO4)₂·8H₂O$ was not found in TEM-EDS examination of the solid phases (Fig. S1). The concentrations of $Sb(III)_{aq}$ in experiments P-0, P-9.5, P-19, P-95, and P-475 were 13.8, 14.9, 15.0, 16.1, and 16.0 mg/L, respectively ([Fig. 2](#page-2-0)a). The increase in $PO_4^{\;3-}$ concentration from 0 to 95 mg/L resulted in gradual release of Sb(III) into solution. Meanwhile, the concentrations of Fe(II)_{aq} in these experiments were below 0.1 mg/L ([Fig. 2b](#page-2-0)) and the decrease in the concentrations of PO_4^{3-} in the experiments P-9.5, P-19, and P-95 at pH 9.0 was only 0.17–0.56 mg/L ([Fig. 2](#page-2-0)c), indicating that FeS was stable and PO_4^{3-} adsorption was

minor. The effect of PO_4^3 ⁻ on the adsorption of As by FeS was reported to be negligible because As(III) was mostly present as As(III)–S(–II)–like species and this binding mechanism was specific to As(III) [\(Niazi and](#page-7-0) [Burton, 2016; Han et al., 2020](#page-7-0)). Similar to As(III), the majority of Sb(III) bound to FeS is suggested to be stable when affected by PO_4^{3-} . Therefore, the small amount of Sb(III) released from solid FeS was likely related to the change of ionic strength.

3.3. XPS spectra of the solid phases after interaction

The XPS Sb-3d spectra of the solid phase samples of the $FeS + Sb(III)$ and FeS + Sb(III) + $PO₄³⁻$ experiments (P-0 and P-95) are shown in [Fig. 5.](#page-5-0) The signal of Sb(III)–O is considered an indication of Sb(III) species of Sb(OH)₃, Sb(OH)₄⁻, or Sb(OH)₂⁺ that were electrostatically adsorbed on the surface of FeS or bound to FeS on the sites of Fe(II) or S (–II), whereas the signal of Sb(III)–S is considered an indication of precipitates of Sb_2S_3 or $Sb(III)$ species binding on the S(-II) sites of FeS.

The occurrence of Sb(III) as Sb(III)–S or Sb(III)–O was found to be closely related to pH. The chemical bond of Sb(III)–S was observed in the solid phases of experiments P-0 and P-95 at pH 5.5 and 7.0 ([Fig. 5](#page-5-0)a and b, d, and e), indicating that the formation of Sb_2S_3 or the binding of Sb (III) on the S(–II) sites of FeS was important under acidic or neutral conditions. Moreover, the Sb(III)–S signal of the pH 5.5 sample was stronger than that of the pH 7.0 sample for experiments P-0 [\(Fig. 5a](#page-5-0) and b) and P-95 [\(Fig. 5d](#page-5-0) and e), indicating that the binding of Sb(III) to S(–II) was more important at lower pH. This result is consistent with the abovementioned notion that Sb₂S₃ formation can be enhanced at lower pH. Additionally, it has been previously reported that Sb(III) was much more importantly bound to FeS on the sites of S(-II) at lower pH (Han [et al., 2018;](#page-7-0) [Li et al., 2021\)](#page-7-0). This trend of Sb(III) binding to FeS with respect to pH agrees well with that of As(III). Previous studies reported that more As could be bound to FeS on S(–II) sites with decreasing pH ([Gallegos et al., 2007\)](#page-7-0), and the formation of As_2S_3 can be enhanced at lower pH ([Wilkin and Ford, 2002; Rodriguez-Freire et al., 2014](#page-7-0)).

For the pH 9.0 samples of experiments P-0 and P-95, the Sb(III)–O signal was observed ([Fig. 5,](#page-5-0) c and f), whereas the Sb(III)–S signal was absent. This is in good agreement with the above result that adsorption was the dominant process responsible for the uptake of Sb(III) by FeS at

Fig. 4. Precipitates of Fe₃(PO₄)₂·8H₂O and Sb₂S₃ in the solid phases of experiments P-95 (a, b, and c: TEM image and EDS spectra of pH 5.5 sample; d, e, and f: TEM image and EDS spectra of pH 7.0 sample) (The signal of Cu, C, and O originated from the support grids for sample).

pH 9.0. The lack of a Sb(III)-S signal supported the notion that precipitation of Sb $_2$ S $_3$ was not possible at pH 9.0 regardless of whether PO $_4{}^3$ was present.

The binding of Sb(III) to S(–II) in the solid phases could be significantly affected by high PO_4^{3-} loading. The Sb(III)–S peak of the solid phases of experiment P-95 was stronger than that of experiment P-0 regarding the experiments at pH 5.5 ([Fig. 5,](#page-5-0) a and d) or 7.0 ([Fig. 5,](#page-5-0) b and e), indicating that the presence of high PO_4^{3-} loading (95 mg/L) enhanced the binding of Sb(III) to S(–II). This is consistent with the above result that high PO $_4^{3-}$ loadings enhanced the formation of Sb $_2$ S $_3$ at pH 5.5 and 7.0. Particularly, for the experiments P-95 at pH 5.5, the signal of the Sb(III)–S bond was strong, whereas the signal of Sb(III)–O was absent ([Fig. 5](#page-5-0)d). This implies that, in the presence of high PO_4^3 loadings, most Sb(III) was likely present as $Sb₂S₃$ precipitates whereas Sb(III) adsorption on FeS was not significant.

For the pH 9.0 samples, the binding of Sb(III)–O can also be affected by PO4 ³[−] . The smaller Sb(III)–O peak of the solid phases of experiment P-95 ([Fig. 5](#page-5-0)f) than that of experiment P-0 [\(Fig. 5c](#page-5-0)) possibly reflected the desorption of Sb(III) resulting from the presence of $PO₄³⁻$. As described above, the release of Sb(III) into solution gradually increased when the concentration of PO_4^{3-} increased to 95 mg/L.

3.4. Precipitation of Sb2S3 and Fe3(PO4)2‧*8H2O*

For the interaction of Sb(III) with FeS at pH 5.5 and 7.0, the precipitation of Sb_2S_3 can be attributed to the competition between $Sb(III)$ and Fe(II) for binding to sulfide ([Han et al., 2018](#page-7-0); [Li et al., 2021\)](#page-7-0). The dissolution or precipitation of a compound is dependent of its solubility product (K_{sp}). The solubility product of Sb_2S_3 (Log K_{sp} = −92.8, Mane [and Lokhande, 2003](#page-7-0)) is much lower than that of FeS (Log $K_{sp} = -27.39$,

Fig. 5. XPS spectra of Sb 3d peaks for the solid phases (a, b, and c: experiments P-0 at pH 5.5, 7.0, and 9.0; d, e, and f: experiments P-95 at pH 5.5, 7.0, and 9.0).

[Jong and Parry, 2003\)](#page-7-0). The difference in solubility product indicates that Sb(III) can possibly outcompete Fe(II) in binding to $S(-II)_{aq}$. The competition of Sb(III) and Fe(II) for $S(-II)_{aq}$ can be described by the following equilibrium reaction between FeS and amorphous Sb_2S_3 .

$$
3 \text{ FeS}_{(s)} + 2 \text{ Sb(OH)}_3 + 6 \text{ H}^+ \rightleftharpoons \text{Sb}_2\text{S}_{3(s)} + 3 \text{ Fe}^{2+} + 6 \text{ H}_2\text{O} \dots \dots \dots \tag{1}
$$

This reaction is dependent of pH. When pH decreases, FeS becomes more soluble ([Wolthers et al., 2005;](#page-8-0) [Han et al., 2018\)](#page-7-0) and releases more S(–II) that subsequently react with Sb(III). Moreover, the stability of $Sb₂S₃$ can increase significantly with decreasing pH [\(Krupp, 1988](#page-7-0); [Spycher and Reed, 1989](#page-7-0); [Olsen et al., 2018](#page-7-0)). Similar to $Sb₂S₃$, the stability of As_2S_3 has also been reported to increase under acidic conditions ([Wilkin and Ford, 2002;](#page-7-0) [Rodriguez-Freire et al., 2014](#page-7-0)). Therefore, the precipitation of Sb_2S_3 in the interaction of Sb(III) with FeS can be enhanced at lower pH. When pH increases, FeS becomes more stable and is more difficult to dissolve. In the pH 9.0 experiments, the concentrations of Fe(II) were close to zero, indicating that FeS did not dissolve. In these experiments, FeS was initially synthesized by addition of Fe(II) and S(–II) at a molar ratio of 1:1. Although the molar ratio of Fe:S in this material could vary, [Rickard et al. \(2006\)](#page-7-0) reported a stoichiometric composition of $\mathrm{Fe}_{1.00\pm0.01}\mathrm{S}$ in which this ratio was very close to 1:1. Therefore, very minor S(–II) could be expected to be available for the formation of $Sb₂S₃$.

The stability fields of FeS and Sb_2S_3 according to reaction (1) are shown in [Fig. 6.](#page-6-0) It can be seen that the conditions of the pH 5.5 and pH 7.0 experiments were favorable for the formation of $Sb₂S₃$. The

conditions of the pH 9.0 experiments were not shown because the concentrations of Fe(II) were close to zero. Anyway, the stability field of $Sb₂S₃$ at pH 9.0 was shown to be much smaller than that at pH 5.5 and pH 7.0. Consistent with the discussion above, precipitates of $Sb₂S₃$ were observed in the pH 5.5 and pH 7.0 experiments, but not observed in the pH 9.0 experiments.

When excess sulfide is available, $Sb₂S₃$ becomes less stable because it can complex with sulfide to form thioantimonite species (e.g., $Sb_2S_4^2$ and HSb₂S₄⁻) under alkaline conditions [\(Polack et al., 2009;](#page-7-0) [Planer--](#page-7-0)[Friedrich and Scheinost, 2011\)](#page-7-0). In the pH 9 experiments, FeS was very stable and $S(-II)_{aq}$ was basically not available (as mentioned above) for the formation of thioantimonite species, so Sb(III) should be mainly present as $Sb(OH)_3$. This is consistent with the result of Olsen et al. [\(2018\).](#page-7-0) They reported that, in a solution containing 3.2 mg/L S(-II)_{aq}, $Sb(OH)$ ₃ was the predominant species from pH 7.5 to 11.8 whereas $H\mathrm{Sb}_2\mathrm{S}_4^-$ was predominant from pH 6.4 to 7.5. In the pH 5.5 and pH 7.0 experiments, partial dissolution of FeS occurred ([Fig. 2b](#page-2-0)) and the concentration of the released S(–II)aq was calculated to be 10.4 and 1.2 mg/L, respectively. A comparison between these data and result of [Olsen](#page-7-0) [et al. \(2018\)](#page-7-0) indicates that, in the pH 7.0 experiments, the presence of $\mathrm{H}{\mathrm{Sb}_2}{\mathrm{S}_4}^-$ could be of significance. However, it seems difficult to identify the presence of thioanimonite species in the pH 5.5 experiments, because the stability of thioantimonite species is much lower at lower pH [\(Krupp, 1988; Olsen et al., 2018\)](#page-7-0).

In aqueous environments, PO_4^{3-} has a potential to react with Fe(II) and form a precipitate of $Fe₃(PO₄)₂·8H₂O$ ([Nriagu, 1972\)](#page-7-0). The formation

Fig. 6. Stability fields for FeS versus $Sb₂S₃$ (adapted from Hockmann et al., [2020\)](#page-7-0). Background NaCl concentration was 0.1 M. Symbols in the elliptical and the rectangular areas indicate the conditions of pH 5.5 and pH 7.0 experiments, respectively.

of Fe₃(PO₄)₂·8H₂O has been observed in lake sediments (Fagel et al., [2005;](#page-7-0) O'[Connell et al., 2015;](#page-7-0) [Rothe et al., 2016\)](#page-7-0) and wastewaters ([Wilfert et al., 2015](#page-8-0); [Li et al., 2018\)](#page-7-0). In a sulfidic system, however, it is difficult for $Fe_3(PO_4)_2.8H_2O$ to be formed because PO_4^{3-} has a lower binding strength to Fe(II) than S(–II) ([Nriagu, 1972](#page-7-0)). This can be reflected by the solubility products of FeS (Log $K_{sp} = -27.39$) and Fe₃(PO₄)₂·8H₂O (Log K_{sp} = -36, [Nriagu, 1972](#page-7-0)). It has been suggested that high activities of Fe(II) and PO $_4^{3-}$, as well as low S(–II) activity, are required for the formation of vivianite in lake sediments ([Fagel et al.,](#page-7-0) [2005;](#page-7-0) O'[Connell et al., 2015](#page-7-0)). Therefore, in the FeS + Sb(III) + $PO₄³$ system, the formation of $Fe₃(PO₄)₂·8H₂O$ is considered possible only when high activities of Fe(II) and PO_4^{3-} are present. The reaction is described below.

$3 \text{ FeS} + 2 \text{ H}_2\text{PO}_4^- + 2 \text{ H}^+ + \text{H}_2\text{O} \leftrightharpoons \text{Fe}_3(\text{PO}_4)_2.8\text{H}_2\text{O}_{(s)} + 3 \text{ H}_2\text{S} \dots$ (2)

Under alkaline conditions, FeS is stable and Fe(II) released into the aqueous phase is very minor, so the formation of $Fe₃(PO₄)₂·8H₂O$ is very difficult. Under acidic and neutral conditions, FeS can dissolve to some extent and release some Fe(II) into aqueous phase, making the formation of Fe₃(PO₄)₂·8H₂O possible when PO₄^{3–} loading is high enough. This explains why precipitates of $Fe₃(PO₄)₂·8H₂O$ were only observed in the experiments at pH 5.5 and 7.0 with high PO_4^{3-} loadings (95 and 475 mg/L). Consistently, [Schoepfer et al. \(2019\)](#page-7-0) reported that a higher PO $_4^3$ loading led to the formation of more vivianite at expense of FeS. The formation of $Fe₃(PO₄)₂·8H₂O$ resulted in the release of more S(-II) and accordingly enhanced the formation of Sb₂S₃. Basically, the adsorption of Sb(III) on Fe3(PO4)2‧8H2O has been very scarcely investigated. [Johnson et al. \(2021\)](#page-7-0) reported the presence of a small amount of Sb(III) on vivianite in the interaction of Sb(V) with vivianite. As shown in [Fig. 4](#page-4-0) and Fig. S2, very little Sb(III) was detected to be bound to $Fe₃(PO₄)₂$. 8H2O when compared to that bound to FeS. Therefore, it is assumed that the contribution of readsorption of Sb(III) on $Fe₃(PO₄)₂·8H₂O$ to the removal of Sb(III)aq was minor.

In the experiments with high PO₄^{3−} loadings, the decrease in PO₄³ concentration at pH 5.5 was found to be similar to that at pH 7.0

([Fig. 2](#page-2-0)c). Consistently, in the TEM examination of the solid phases of the experiments with high $\mathrm{PO_4}^{3-}$ loadings, $\mathrm{Fe_3(PO_4)_2\cdot 8H_2O}$ was observed in the pH 5.5 sample at a similar frequency as in the pH 7.0 sample, although the dissolution of FeS at pH 5.5 was stronger than that at pH 7.0. This means that the presence of a high PO_4^{3-} loading at pH 5.5 and 7.0 resulted in a similar yield of Fe3(PO4)2‧8H2O. This result is suggested to be related to the pH-dependent stability of $Fe₃(PO₄)₂·8H₂O$. With changes in pH, phosphate species transform at different pKa values and the stability of $Fe₃(PO₄)₂·8H₂O$ can be influenced (Palansooriya et al., [2021\)](#page-7-0). [Li et al. \(2018\)](#page-7-0) reported that, although $Fe_3(PO_4)_2·8H_2O$ was stable in the solid phase at pH 6, it was largely dissolved when the pH was lowered to 5 and was mostly soluble when the pH was further decreased to 3. Overall, the stability of $Fe₃(PO₄)₂·8H₂O$ decreased with decreasing pH, but the concurrent stronger dissolution of FeS at lower pH could compensate for the formation of $Fe₃(PO₄)₂·8H₂O$.

The mitigation of Sb(III) mobility in FeS-containing system by the high PO_4^{3-} loading is possibly of minor importance for most environmental systems because of the very high Sb(III) and $PO₄^{3–}$ concentrations in the present study. In some sulfidic mine tailings sites, however, PO₄^{3–} has been increasingly utilized to stabilize metal(loid)s ([Munks](#page-7-0)[gaard and Lottermoser, 2013](#page-7-0); [Saavedra-Mella et al., 2019\)](#page-7-0). In anoxic layers of these mine tailings, high dosages of $PO₄^{3−}$ may encounter the presence of FeS and high concentrations of soluble metal(loid)s. For example, [Ashley et al. \(2003\)](#page-7-0) reported Sb concentration of 55 mg L^{-1} in tailings dam seepage water in an Sb (stibnite) deposit at Hillgrove, Australia. In these settings, the effect of high loadings PO_4^{3-} on the mobility of Sb(III) can be of major importance.

4. Conclusions

In the interaction of Sb(III) with FeS, the uptake of Sb(III) could be significantly affected by PO_4^{3-} . This impact was closely related to pH and $PO₄³⁻$ concentration. Under slightly acidic (pH 5.5) or neutral conditions (pH 7.0), high PO_4^{3-} loadings (95 and 475 mg/L) enhanced the uptake of Sb(III) due to the formation of $Fe₃(PO₄)₂·8H₂O$, which enhanced the dissolution of FeS and consequently the precipitation of Sb₂S₃. However, low PO₄³⁻loadings (9.5 and 19 mg/L) did not affect the mobility of Sb(III) because $Fe₃(PO₄)₂·8H₂O$ was not likely to be formed. Under alkaline conditions (pH 9.0), the addition of $PO₄^{3–}$ only resulted in a minor release of Sb(III) into aqueous phase, because the interaction of Sb(III) with FeS was suggested to be dominated by the adsorption that could not be readily affected by PO_4^3 ⁻.
