ARTICLE INFO

ABSTRACT

The Paleo-Tethyan arc belt is host to a small number of porphyry Cu deposits the key controls on which remains poorly understood. It has been hypothesized that the Paleo-Tethyan arc magmas were reduced and therefore less fertile for porphyry Cu formation but few studies have been conducted to directly assess the magmatic oxygen fugacity. We investigate the magma fertility of eastern Paleo-Tethyan arc igneous rocks in the Sanjiang region, SW China, represented by the Maoding (268.3 ± 2.3 Ma), Suwalong (275.6 ± 1.4 Ma to 264.7 ± 1.4 Ma) and Baimaxueshan (255.7 ± 1.5 Ma to 249.3 ± 1.1 Ma) granitoids. They have geochemical features consistent with typical continental arc rocks, formed from partial melting of the mantle wedge, with increasing contamination of crust-derived melts over time. The presence of amphibole, high Sr/Y ratios (35 ± 20, $n = 17$), and lack of negative Eu anomalies ($Eu_N/Eu_N^* = 1.04 \pm 0.3$, n = 17) are consistent with derivation from hydrous magmas. Zircons from the intrusive rocks have relatively low Eu_N/Eu_N^* (mostly <0.4) ratios and calculated ΔFMQ values (-2.1 ± 1.2, $n = 86$). Combined with apatite microphenocrysts with extremely low sulfur contents (< 0.12 wt% SO_3), it suggests that the intrusions originated from water-rich but reduced arc magmas, that were less fertile for porphyry Cu formation. Our study highlights that magmatic fO_2 is probably a critical control on the prospectivity of arc systems and confirms that zircon and apatite compositions can be used to evaluate porphyry Cu fertility.

1. Introduction

The genetic link between subduction, arc magma fertility, and the formation of porphyry Cu $\pm$ Au $\pm$ Mo deposits has been widely discussed in recent decades (Cooke et al., 2005; Richards, 2003; Sillitoe, 2010; Sun et al., 2015). In general, arc magmas are moderately oxidized (ΔFMQ +1 to +2, where ΔFMQ is the value relative to fayalite-magnetite-quartz buffer in log fO_2 units), are enriched in water (> 4 wt%), sulfur (>1000 ppm), and chlorine (>3000 ppm), and are derived from the continuous dehydration of subducted oceanic slabs (Evans and Tomkins, 2011; Kelley and Cottrell, 2009; Richards, 2015a). These magmas allow the transport of economically important metals (Cu and Au) in the melts and the subsequently exsolved hydrothermal fluids, potentially leading to the formation of sulfide-rich ores (Audétát and Simon, 2012; Hou et al., 2015; Zhu et al., 2018).

Arc magmas generally have the potential to form porphyry deposits, but not all magmatic arcs host economic porphyry Cu deposits (Richards, 2003). Possible reasons for this include poor preservation, reduced magmas that result in early sulfide saturation and chalcophile metal loss, and lack of a focus for hydrothermal fluids (Richards, 2013; Sillitoe, 2018). The Paleo-Tethyan arc which stretches for over 10,000 km from the Carpathians–Balkans, through Turkey, Iran, Pakistan, Tibet–Sanjiang Region of southwest China, and IndoChina is host to only a small number of porphyry Cu deposits (Richards, 2015b; Richards and Şengör, 2017). Richards and Şengör (2017) suggested that the lack of porphyry Cu deposits may be attributed to the presence of reduced arc magmas, as the Paleo-Tethyan Ocean was closed during the Permian and thus isolated from global oceanic circulation. However, others have argued that the Paleotethys was an open ocean and not anoxic, which would lead to a higher potential for porphyry Cu deposits in the Paleo-Tethyan arc belt (Wang et al., 2020; Yang et al., 2011). The competing views are possible because of the limited number of studies that directly constrain the magma fertility, particularly the oxidation state (fO_2) of the Paleo-Tethyan arc magmas. It is difficult to evaluate magmatic fO_2
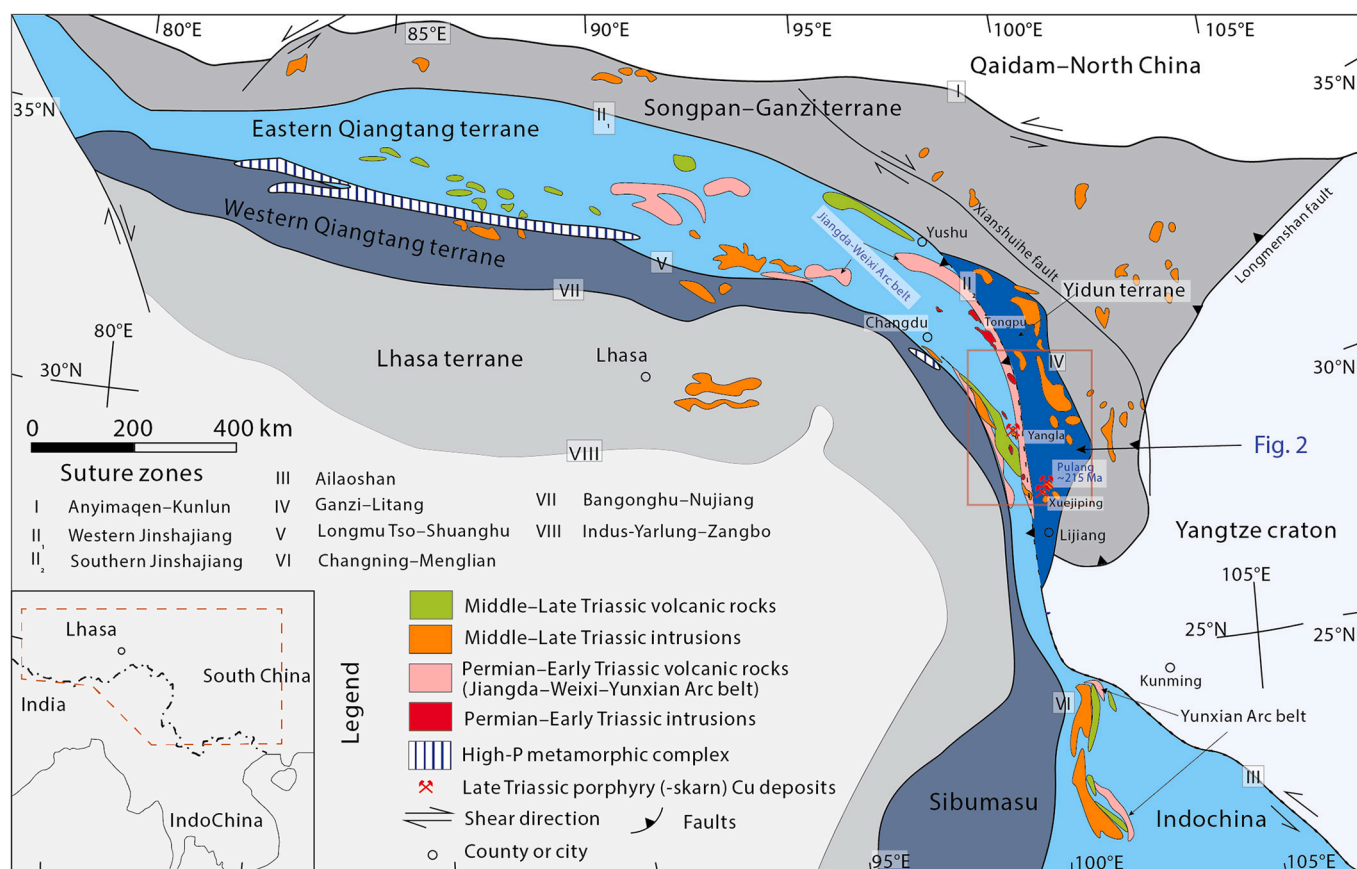

Fig. 1. Tectonic framework of the Sanjiang region, SW China showing the major terranes, suture zones, arc belts, Permian to Triassic igneous rocks, and locations of Late Triassic porphyry Cu deposits (Modified from Yang et al., 2014; Xu et al., 2015; Xin et al., 2018).

and volatile (H₂O-S-Cl) contents quantitatively in whole-rock samples. But the recent use of the accessory minerals zircon and apatite to assess porphyry Cu fertility has demonstrated that his technique can be widely applied (Lu et al., 2016; Zhu et al., 2018).

The Sanjiang region in SW China preserves a number of Late Carboniferous to Permian arc-related igneous rocks, associated with the subduction of the eastern Paleo-Tethyan Ocean (Metcalfe, 2021; Mo et al., 1993; Wang et al., 2018a; Xu et al., 2015; Yang et al., 2011), but coeval economic porphyry Cu deposits are rare (Richards, 2015b). Generally, porphyry Cu deposits (e.g., the giant Pulang Cu deposit) are found on the eastern margin of the Tethyan orogen, where they formed at ~216 Ma, significantly postdating closure of the Paleotethys (before ~230 Ma; Cao et al., 2019; Wang et al., 2018a; Wang et al., 2021). Furthermore, most studies focused on postcollisional Triassic granitoids, and petrogenesis of typical arc magmatism remains not well understood. In this contribution, we investigate the petrogenesis of Paleo-Tethyan arc igneous rocks and evaluate their magma fertility, with combination of whole-rock geochemistry and zircon and apatite compositions, and confirm that (1) the arc magmas were derived from the mixing of mantle and variable degree of crustal magmas, (2) they were indeed relatively reduced and therefore less fertile for porphyry Cu formation, and (3) compositions of zircon and apatite can be used as a tracer for porphyry Cu fertility.

2. Geological background

The Paleo-Tethyan Ocean opened along the northern margin of Gondwana during the early Late Paleozoic, and was then gradually consumed by subduction under the Eurasian continent prior to the mid-Mesozoic (Metcalfe, 2021; Wang et al., 2018a; Zhao et al., 2018; Zhu et al., 2013). The Sangjiang region forms the eastern segment of the Tethyan orogen, now on the southeastern margin of the Tibetan Plateau (Fig. 1). From west to east, the Sanjiang comprises the Western (South) Qiangtang, Eastern (North) Qiangtang–Indochina, Yidun, and Song-pan–Ganzi terranes (Fig. 1). They are separated by three major NW-trending suture zones, which are from west to east the Longmu Tso-Shuanghu–Changning-Mengliang, Jinshajiang–Ailaoshan, and Gan-zi–Litang (Fig. 1).

The Paleo-Tethys Ocean in the Sanjiang region can be divided into southern and northern branches (Zhao et al., 2018). It is generally accepted that the Longmu Tso-Shunaghu suture zone represents the closure of the main branch of the southern Paleo-Tethys Ocean, separating the Eastern Qiangtang terrane of Cathaysian affinity and the Gondwana-derived Western Qiangtang terrane (Li et al., 2006; Wang et al., 2018a; Yang et al., 2011; Zhu et al., 2013). The suture zone is characterized by Carboniferous and Permian ophiolites and an ~500-km long high-pressure metamorphic belt with an assemblage of Triassic eclogites and blueschists (Li et al., 2006; Zhang et al., 2011). To the south, the Longmu Tso-Shunaghu suture zone might connect with the Changning–Menglian suture (Deng et al., 2014; Metcalfe, 2021; Wang et al., 2018a). The eastward subduction (in present coordinates) of the main Paleo-Tethyan Ocean floor likely generated the Permian to Early Triassic S-trending Jiangda (Jomda)–Weixi–Yunxian arc belt in the Eastern Qiangtang terrane (Fig. 1; Yang et al., 2014; Xin et al., 2018). The southern Paleo-Tethyan ocean basin probably closed circa 250–230 Ma, leading to the collision of the Eastern Qiangtang with the Western Qiangtang, and the Sibumasu with the Indochina terranes (Wang et al., 2018a; Zhao et al., 2018).

To the east of the Longmu Tso–Shunaghu suture zone, the Jin-shajiang (Jinsha) suture zone extends over 2000-km and can be divided
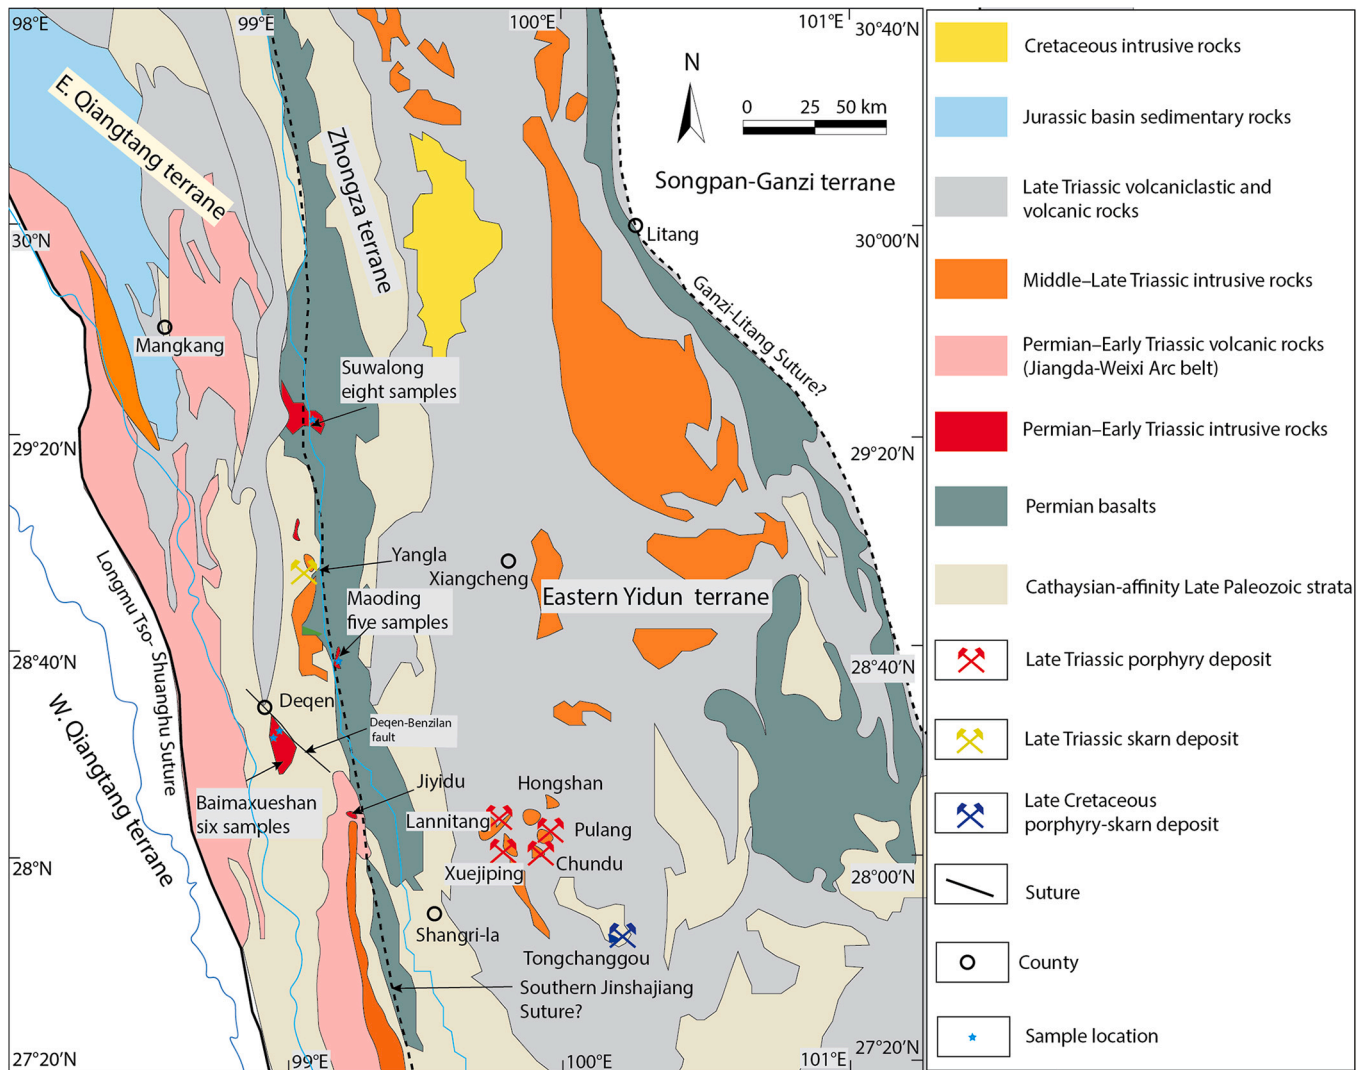

Fig. 2. Simplified geological map of the Eastern Qiangtang and Yidun terranes and the adjacent area showing the major suture zones of the Paleo-Tethyan Ocean (i. e., Longmu Tso–Shuanghu Suture), the granitic intrusions related to Paleo-Tethyan subduction (i.e., Maoding, Baimaxueshan, and Suwalong intrusions), and locations of Late Triassic porphyry Cu deposits (Modified from Yang et al., 2014). Abbreviations of blocks: E. Qiangtang = Eastern Qiangtang, W. Qiangtang = Western Qiangtang.

into two segments (Yang et al., 2014). The western segment defines the boundary between the Eastern Qiangtang and Songpan–Ganzi terranes, and probably records the closure of the Songpan–Ganzi Ocean or Mianlue Ocean, which was considered to be the northern branch of the Paleo-Tethyan Ocean (Zhao et al., 2018). It closed at 240–220 Ma, leading to the collision of the Eastern Qiangtang–Indochina–South China blocks with the North China and Qaidam blocks (Zhao et al., 2018). The southern segment of the Jinshajiang suture lies between the Eastern Qiangtang and western Yidun terranes (Figs. 1–2), but the nature of the suture remains a topic of debate. It might represent a remnant of the Jinshajiang Paleo-Tethyan Ocean marked by a series of ophiolitic fragments, and extends south to the Ailaoshan suture (Mo et al., 1993; Zi et al., 2012a) or a small back-arc/intra-arc basin formed by the east-dipping subduction of the main Paleo-Tethyan oceanic lithosphere (Wang et al., 2018a; Zhao et al., 2018).

The Jiangda–Weixi Arc belt is the focus of this study, defined by a ∼ 400-km long series of NW-trending Permian to Lower Triassic volcaniclastic rocks in the southern part of the Eastern Qiangtang terrane (Fig. 1; Mo et al., 1993; Yang et al., 2011, 2014; Xin et al., 2018). It preserves the most representative Paleo-Tethyan arc igneous rocks in the Sanjiang region, probably associated with subduction of the main Paleo-

Tethyan Ocean. The arc-related rocks comprise four lithological units with two suites of andesite, dacite, rhyolite, and minor basalt separated by two layers of limestone and shale (Xin et al., 2018; Yang et al., 2014). Several arc-related Permian to Early Triassic granitic batholiths are also found in the region (Wu et al., 2013; Yang et al., 2011). Late Triassic to Jurassic limestone and volcanic-siliciclastic rocks occur above an angular unconformity, which caps the Jiangda–Weixi Arc rocks (Li et al., 2006; Yang et al., 2014; Zhang et al., 2011). In addition, a number of south-trending Late Triassic post-orogenic granitoids (e.g., Jiaren, Dongdashan, and Ludian) occur along both sides of the Eastern Qiangtang terrane (Figs. 1–2; Zhu et al., 2011; Peng et al., 2015). No porphyry Cu deposits associated with Jiangda–Weixi arc magmatism have yet been found. The major porphyry mineralization in the Sanjiang region occurs at ∼216 Ma within the Yidun terrane (Figs. 1–2), unrelated to the Paleo-Tethyan subduction (Wang et al., 2021). These include the Late Triassic Pulang (1625 Mt. @ 0.34% Cu and 0.18 g/t Au), Xuejiping (54 Mt. @ 0.53% Cu), and Lannitang (36 Mt. @ 0.5% Cu) Cu ± Au deposits, as well as a few porphyry Cu—Au prospects (Figs. 1 and 2; Deng et al., 2014; Cao et al., 2019; Yang and Cooke, 2019; Wang et al., 2021).
Fig. 3. Representative cross-polarized light photomicrographs showing (A–B) the Baimaxueshan granitoid (BMXS17–5, BMXS17–7), (C) the Suwalong (SWL17–3), and (C) Maoding (MD12–1) granodiorites, with coarse-grained amphibole and biotite; and backscattered electron images showing ilmenite inclusions within plagioclase or amphibole grains for (E) Suwalong (SWL17–8), and (F) Maoding (MD12–1) granodiorites. Abbreviations: Amp = amphibole, Bi = biotite, Ilm = ilmenite, Kfs = K-feldspar, Pl = plagioclase, Qtz = quartz.

3. Samples and analytical methods

A series of Permian to Early Triassic granitoids have been emplaced in the Jiangda–Weixi Arc belt, including, from north to south, the Tongpu, Suwalong, Maoding, Baimaxueshan, and Jiyidu plutons (Jian et al., 2003; Wu et al., 2013; Yang et al., 2011; Zi et al., 2012b). Samples were collected from the Baimaxueshan, Suwalong, and Maoding intrusions (Fig. 2). The Baimaxueshan pluton is located ~30 km south of Deqin county, Yunan province, with an outcrop area of ~135 km². It intruded the Upper Permian schists and marbles (Zi et al., 2012a), and is mainly composed of medium-grained granodiorite, with 35–40 vol% plagioclase, 20–25 vol% K-feldspar, 25 vol% quartz, 5–10 vol% amphibole, and 5 vol% biotite (Fig. 3A–B). Zircon U—Pb dating yielded a relatively large range of ages between 255 Ma and 239 Ma, consistent with the Paleo-Tethyan subduction or the early stage of collision (He et al., 2018; Jian et al., 2003; Zi et al., 2012a).

The Suwalong intrusion is located on the east bank of the Jinshajiang River, ~70 km south of Batang county, Sichuan province, with an

outcrop area of ~30 km² (Fig. 2). It intruded Devonian to Carboniferous schist and marble, and is cut by the S-trending Suwalong–Wubalong fault (SCBGMR, 1977). The intrusive rocks range from biotite granite to granodiorite, with medium- to fine-grained textures, and are composed of K-feldspar (40–45 vol%), plagioclase (25 vol%), quartz (20–25 vol%), biotite (5 vol%), and amphibole (5 vol%; Fig. 3C; SCBGMR, 1977).

The Maoding pluton (~1 km²) is located ~2 km southeast of the Late Triassic Jiaren batholith (~150 km²), and is crosscut by the Jinshajiang River (Fig. 2; Zhu et al., 2011). It is a fine-grained granodiorite composed of plagioclase (40–45 vol%), K-feldspar (20 vol%), quartz (20–25 vol%), amphibole (5 vol%), and biotite (5 vol%, locally showing gneissic structure; Fig. 3D), intruding the the Devonian carbonate and sandstone sequences. All the three granitoids above host ilmenite grains, typical of ilmenite-series granite (Figs. 3E–F).

Twenty-one samples from the Baimaxueshan, Suwalong, and Maoding granitoids were collected from outcrop. Detailed descriptions and locations are listed in digital Appendix Table A1. Eighteen fresh samples from the three granitoids plutons were selected for whole-rock
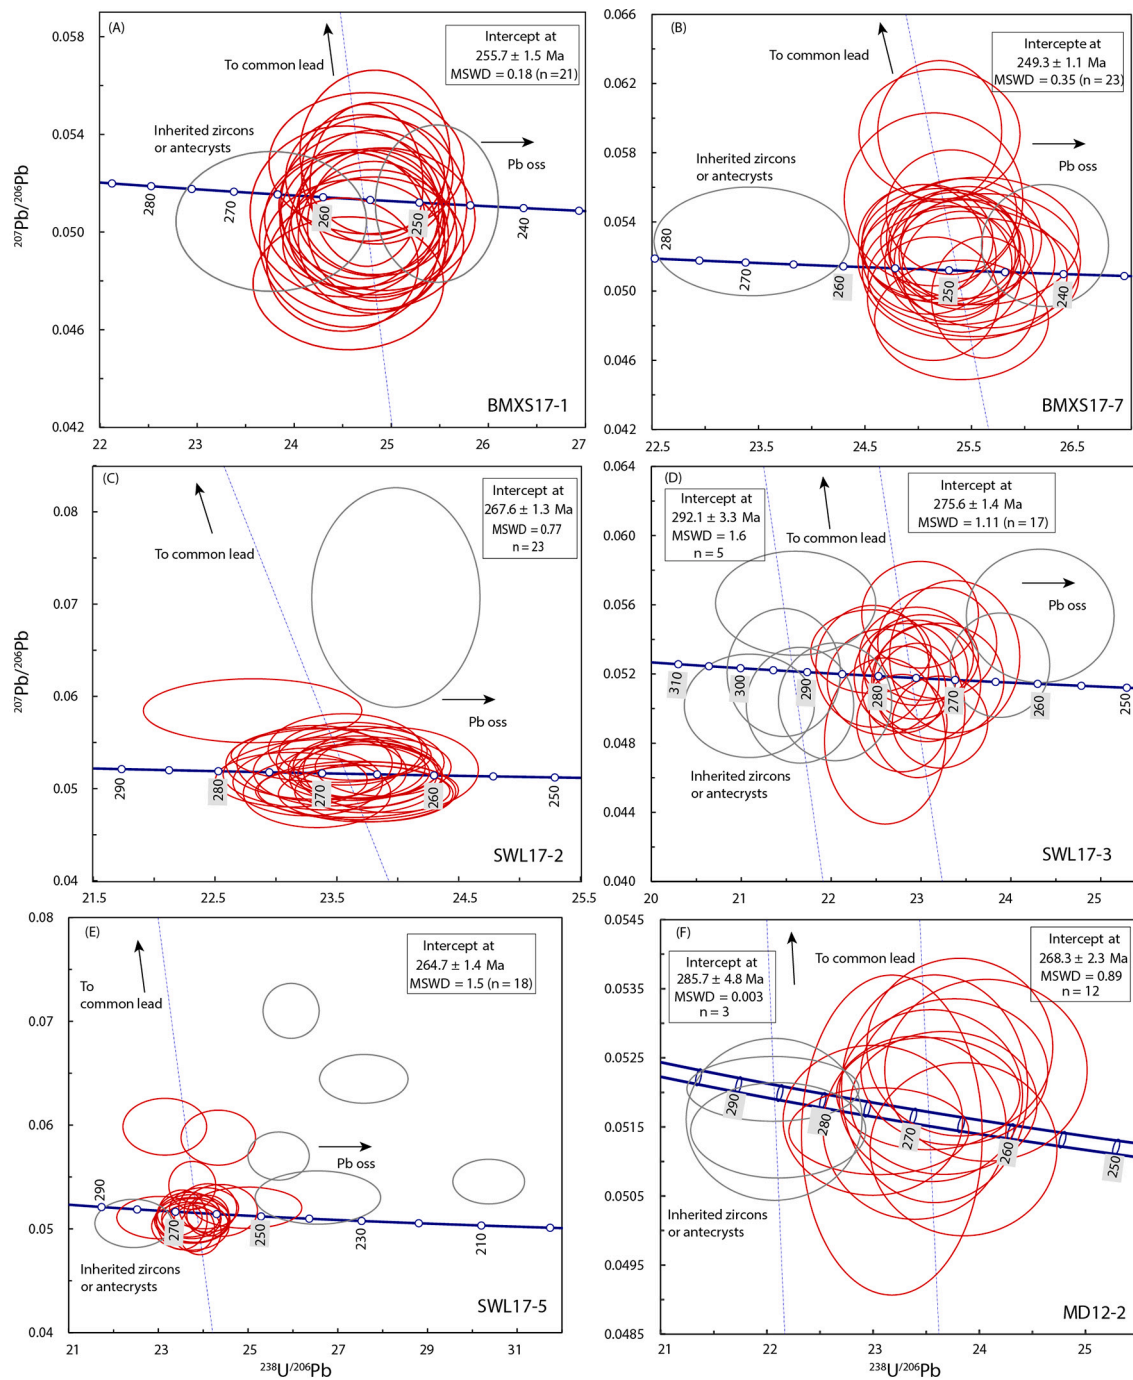

Fig. 4. Zircon U—Pb Tera-Wasserburg concordia diagrams for the Baimaxueshan, Suwalong, and Maoding granitoids (Tera and Wasserburg, 1972). Samples (A) BMXS17–1, (B) BMXS17–7, (C) SWL17–2, (D) SWL17–3, (E) SWL17–5, and (F) MD12–2. Gray ellipses are analyses excluded from the age calculation (see text for details). Uncertainty ellipses and calculated ages are shown at 2σ.

geochemical and electron microprobe (apatite) analyses, with six of them (three from Suwalong, one from Maoding, and two from Baimaxueshan) also prepared for zircon U—Pb dating and trace element measurements. One sample from the Maoding intrusion was used for zircon Hf—O as well. Detailed analytical methods can be found in Appendix 1.

4. Results

4.1. Zircon U—Pb isotopic results

Zircon U—Pb data for the Baimaxueshan and Suwalong granitoids are presented in digital Appendix Tables A2, and A3 for the Maoding granitoid. All the results are also illustrated in Fig. 4. Samples BMXS17–1 and BMXS17–7 were obtained from the Baimaxueshan pluton. Analyzed zircon grains from the two samples both show tightly clustered ages, mostly with low common lead contents (Figs. 4A–B). Sample BMXS17–1 yielded an intercept age of 255.7 ± 1.5 Ma (MSWD

Fig. 5. (A) Total alkali-silica diagram (Middlemost, 1994), (B) Sr/Y ratios vs. Y, (C) SiO_2 vs. A/CNK [molar Al_2O_3/(CaO + Na_2O + K_2O)], and (D) SiO_2 vs. Eu_N/Eu_N^* for the Baimaxueshan, Suwalong, and Maoding granitoids. Normalizing values from Sun and McDonough (1989).

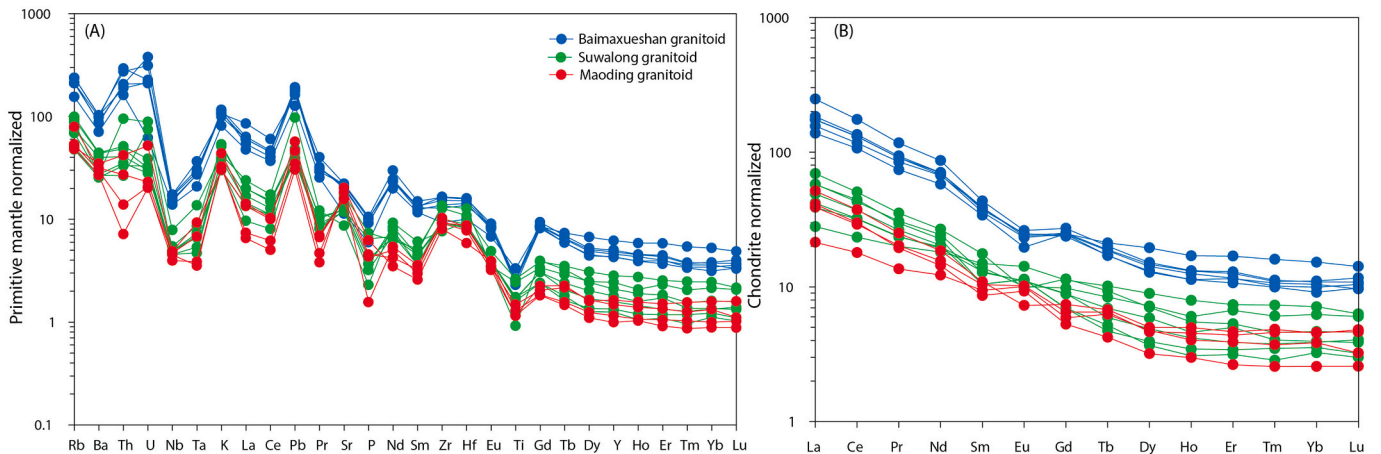

Fig. 6. (A) Primitive mantle-normalized trace element and (B) chondrite-normalized rare earth element diagrams for the Baimaxueshan, Suwalong, and Maoding granitoids. The normalizing values for primitive mantle and chondrite are from Sun and McDonough (1989).

= 0.18; Fig. 4A) based on 21 of 25 grains, consistent with weighted mean $^{206}Pb/^{238}U$ ages of 255.5 ± 1.5 Ma (MSWD = 0.13). The four excluded grains include two with much older ages (apparent $^{206}Pb/^{238}U$ ages = 329 ± 7.2 Ma and 1075 ± 34.3 Ma, respectively; digital App. Table A2), and one grain having slightly older $^{206}Pb/^{238}U$ age of 266 ±

8.8 Ma, indicative of xenocrysts or antecrysts (Fig. 4B). The other zircon grain yielded a slightly younger $^{206}Pb/^{238}U$ age (248 ± 5.0 Ma), probably explained by lead loss (Fig. 4B). Twenty-five zircon grains from sample BMXS17–7 were selected for analyses, and one xenocrystic zircon grain was found, with a $^{206}Pb/^{238}U$ age of 269.4 ± 8.4 Ma

Notes: [1]Rb, Sr, Sm, and Nd concentrations from Table 1; $T_{DM1} = (1/\lambda) \times Ln[((^{143}Nd/^{144}Nd)_{sample}-(^{143}Nd/^{144}Nd)_{DM})/((^{147}Sm/^{144}Nd)_{sample}-(^{147}Sm/^{144}Nd)_{DM} + 1)]$ and $T_{DM2} = T_{DM1} - (T_{DM1} - t) \times ((f_{cc} - f_s)/(f_{cc} - f_{DM}))$ calculation for T_{DM2} following assuming of Keto and Jacobsen (1987) where $f_{cc} = -0.4$, $f_{DM} = 0.0859$. See Appendix 1 for the $^{143}Nd/^{144}Nd$ and $^{147}Sm/^{144}Nd$ values of present day chondrite and depleted mantle.

Fig. 7. $\varepsilon_{Nd}(t)$ vs. initial $^{87}Sr/^{86}Sr$ ratios for the Baimaxueshan, Suwalong, and Maoding granitoids at $t = 250$ Ma. Data from the Baimaxueshan from Zi et al. (2012a), He et al. (2018), and this study. The mantle field represented by the Longmu Co–Shuanghu ophiolites after Zhai et al. (2019); the Eastern Qiangtang curst field represented by granite after Peng et al. (2015); global subducting sediment (GLOSS) after Plank and Langmuir (1998). The parameters used in the mixing calculations: mantle-derived melt, 164 ppm Sr, 6.69 ppm Nd, initial $^{87}Sr/^{86}Sr = 0.7041$, $\varepsilon_{Nd}(t) = 4.6$; crustal-derived melt, 131 ppm Sr, 39.1 ppm Nd, initial $^{87}Sr/^{86}Sr = 0.7275$, $\varepsilon_{Nd}(t) = -12.1$.

(digital App. Table A2). Another crystal with $^{206}Pb/^{238}U$ age of 241.6 ± 4.4 Ma might be caused by lead loss (Fig. 4B). The remaining 23 zircon grains intersected the concordia line at 249.3 ± 1.1 Ma (MSWD = 0.35; Fig. 4B), in good agreement with the weighted mean $^{206}Pb/^{238}U$ age of 249.7 ± 1.1 Ma (MSWD = 0.41). These intercept ages are considered to be the emplacement ages for the Baimaxueshan intrusion. They are consistent with recently published zircon U—Pb ages (He et al., 2018; Zi et al., 2012a), and collectively defined a magmatic duration of ~6 m.y.

from 255.7 ± 1.5 Ma to 249.3 ± 1.1 Ma for Baimaxueshan.

Samples SWL17–2, SWL17–3, and SWL17–5 were collected from the Suwalong granitoid. For sample SWL17–2, excluding one xenocryst with an older $^{206}Pb/^{238}U$ age of 545 ± 38.8 Ma (digital App. Table A2) and one grain with a younger discordant age due to lead loss (apparent $^{206}Pb/^{238}U$ age = 263.3 ± 6.1 Ma), the remaining 23 crystals yielded a homogeneous age population with low common lead contents (Fig. 4C). Regression of this population yielded an intercept age of 267.6 ± 1.3 Ma (MSWD = 0.77; Fig. 4C), similar to the weighted mean $^{206}Pb/^{238}U$ age (267.8 ± 1.3 Ma; MSWD = 0.83). Twenty-five crystals from sample SWL17–3 were selected for analyses with one xenocryst yielding an older $^{206}Pb/^{238}U$ age of 426.4 ± 23.8 Ma (digital App. Table A2). Twenty-two grains show two age groups on a $^{206}Pb/^{238}U$ age histogram and the concordia diagram (Fig. 4D). One group intercepts the concordia line at 292.1 ± 3.3 Ma (MSWD = 1.6; $n = 5$), whereas a younger group yielded an intercept age of 275.6 ± 1.4 Ma (MSWD = 1.11; $n = 17$). The young age might best represent the emplacement age of the rock, consistent with their weighted mean $^{206}Pb/^{238}U$ age (275.5 ± 1.4 Ma, MSWD = 1.04). The older group is likely of antecrystic or inherited origin. The remaining two crystals plotted to the right of the younger group reflecting lead loss (Fig. 4D). Sample SWL17–5 has a relatively scattered distribution of individual zircon spot ages, probably caused by an antecryst or inherited zircon grain ($^{206}Pb/^{238}U$ age = 281.0 ± 8.6 Ma), and six young crystals with lead loss (digital App. Table A2; Fig. 4E). The young zircon grains show relatively high common lead contents, with variable $^{206}Pb/^{238}U$ ages from 246 to 115 Ma (digital App. Table A2). The remaining 18 crystals yielded low amounts of common lead and intercept the concordia line at 264.7 ± 1.4 Ma (MSWD = 18; Fig. 4E), in good agreement with the weighted mean $^{206}Pb/^{238}U$ age of 264.6 ± 1.4 Ma (MSWD = 1.4). The intercept ages for the Suwalong intrusion are interpreted to be its crystallization ages, and define a ~ 11-m.y. span of magmatism from 275.6 ± 1.4 Ma to 264.7 ± 1.4 Ma.

Sample MD12–2 was obtained from the Maoding intrusion. Fifteen analyzed zircon grains show two age groups, both with low common lead contents (digital App. Table A3; Figs. 4F). One group of three crystals yielded an intercept age of 285.7 ± 4.8 Ma (MSWD = 0.003), and the other group intercepts the Concordia line at 268.3 ± 2.3 Ma (MSWD = 0.89; Fig. 4F). The older group could represent antecrysts or

[1] Age results see Table A3; "n/a" = no data; $T_{DM1} = (1/\lambda) \times Ln[((^{176}Hf/^{177}Hf)sample-(^{176}Hf/^{177}Hf)_{DM})/((^{176}Lu/^{177}Hf)sample-(^{176}Lu/^{177}Hf)_{DM}+1)]$. See Appendix 1 for the $^{177}Hf/^{176}Hf$ and $^{177}Lu/^{176}Hf$ values of present day chondrite and depleted mantle.

inherited zircon grains. The young age might best represent the crystallization age of the intrusion, consistent with the weighted mean $^{206}Pb/^{238}U$ age of 268.2 ± 2.3 Ma (MSWD = 0.88).

In summary, the three granite intrusions were emplaced between ~275–249 Ma.

4.2. Whole-rock major and trace elements

Whole-rock geochemical compositions for 20 samples of the three Permian to Early Triassic granitoids are reported in Table 1 and illustrated on Figs. 5–6. The Baimaixueshan, Suwalong, and Maoding intrusions are mostly felsic (SiO_2 = 61.78–73.15 wt%), calc-alkaline to high-K calc-alkaline ($K_2O + Na_2O$ = 4.48–6.17 wt%) and have compositions from diorite to granodiorite (except SWL17–5 plotted in the field of granite; Fig. 5A). They are metaluminous to slightly peraluminous, with A/CNK ratios [molar $Al_2O_3/(CaO + Na_2O + K_2O)$] from 0.93 to 1.07 (Fig. 5C). On primitive mantle-normalized trace element and chondrite-normalized rare earth element (REE) diagrams, all the granitoid rocks show similar patterns (Fig. 6), characterized by high contents of large-ion-lithophile elements (LILEs: Ba, Rb, U, Th, K) and light rare earth elements (LREE), with low concentrations of high-field-strength elements (HFSEs: Nb, Ta, Ti, Zr, Hf). Middle to heavy rare earth elements (MREE, HREE; La/Yb = 17.9 ± 7.6, n = 17) are relatively depleted, with flat- to listric-shaped patterns (Gd/Yb = 2.5 ± 0.5, n = 17). All the samples have relatively high but variable Sr/Y ratios (35 ± 20, n = 17; Fig. 5B), with slightly negative to positive Eu anomalies ($Eu_N/Eu_N* = Eu_N/(Sm_N \times Gd_N)^{0.5}$ = 1.04 ± 0.3, n = 17; Fig. 5D).

4.3. Whole-rock Sr—Nd isotopes

New Sr—Nd isotope data for the Baimaxueshan, Suwalong, and Maoding intrusions are presented in Table 2 and Fig. 7. Two samples from the Baimaxueshan granite have initial Sr isotope ratios of 0.7097 and 0.7128, coupled with negative $\varepsilon_{Nd}(t)$ values of −6.7 and − 10.7. The Suwalong intrusion has low initial Sr isotope ratios from 0.7043 to 0.7057 [$(^{87}Sr/^{86}Sr)_t$ = 0.7049 ± 0.0005, n = 5; t = 250 Ma), with positive $\varepsilon_{Nd}(t)$ values of +0.4 − +2.4 (1.5 ± 0.6, n = 5). The Maoding has a narrow range of initial Sr isotope ratios from 0.7043 to 0.7048 [$(^{87}Sr/^{86}Sr)_t$ = 0.7045 ± 0.0002, n = 4; t = 250 Ma] and $\varepsilon_{Nd}(t)$ values from 1.4 to 2.8 (2.3 ± 0.6, n = 4).

4.4. Zircon Hf—O isotopes

New zircon Hf—O isotope compositions for the Maoding intrusion are presented in Table 3 and Fig. 8. They show homogenous $\varepsilon_{Hf}(t)$ values of 14.3 ± 0.6 (weighted mean values, 2σ; n = 19), with young two-stage Hf model ages of 287 ± 82 Ma (n = 19). Maoding has relatively low zircon $\delta^{18}O$ ratios from 5.6‰ to 7.9‰ (avg. = 6.3 ± 0.6‰, n = 15; Table 3).

4.5. Zircon and apatite compositions

The compositions of zircon and apatite from the Baimaxueshan, Suwalong, and Maoding granitoids are listed in digital Appendix Tables A4 and A5, respectively.

4.5.1. Zircon trace element compositions

Twenty-five trace element spot analyses were obtained on zircon for each sample from the Baimaxueshan (BMXS17–1 and BMXS17–7) and Suwalong (SWL17–2, SWL17–3, SWL17–5) intrusions. For the Maoding intrusion (MD12–2), fifteen zircon grains were analyzed (digital App. Table A4).

The remaining analyses for the three granitic intrusions have high HREE and low LREE concentrations, with negative Eu and positive Ce anomalies (Fig. 9). These REE patterns (ΣREE = 158–2515 ppm) with Th/U ratios above 0.1 (0.15–0.56) are consistent with igneous zircons

**Fig. 8.** (A) $\varepsilon_{Hf}(t)$ and (B) $\delta^{18}O$ values vs. U—Pb ages of zircon grains from the Baimaxueshan, Suwalong, and Maoding granitoids. Data sources for the Baimaxueshan intrusion from Zi et al. (2012a) and He et al. (2018). The light gray band in B represents the range of igneous zircons in high-temperature equilibrium with the mantle ($\delta^{18}O = 5.3 \pm 0.6‰$, 2σ; Valley et al., 1998). Zircon $\delta^{18}O$ values above 6.5‰ indicate significant contamination of supracrustal material.

(Hoskin and Schaltegger, 2003).

Titanium-in-zircon temperatures were calculated using the method of Ferry and Watson (2007); T_{Zr}; Fig. 10A)). Because of the existence of quartz and titanite in the host intrusions, it is assumed that log $a_{SiO2} = 1$ and log $a_{TiO2} = 0.7$. The Baimaxueshan zircon grains have the lowest T_{Zr} values of 704 ± 29 °C (range = 644°–766 °C, n = 17), with Eu_N/Eu_N^* of 0.36 ± 0.12 (range = 0.20–0.56, n = 17). Zircon grains from the Suwalong intrusion have T_{Zr} values of 788 ± 30 °C (range = 682°–851 °C, *n* = 54) and Eu_N/Eu_N^* ratios of 0.26 ± 0.07 (range = 0.15–0.47, n = 54). Zircon grains from the Maoding intrusion yielded calculated temperatures of 725 ± 38 °C ($T_{Zr} = 660°–781$ °C, *n* = 22) and Eu_N/Eu_N^* values of 0.28 ± 0.12 (range = 0.15–0.47, n = 15).

4.5.2. Apatite compositions

The SO_3 analyses of igneous apatite are provided in digital Appendix Table A5 and Fig. 11. All the analyzed apatite microphenocrysts are enclosed within primary minerals including amphibole, plagioclase, and biotite (Fig. 11). None of them contain patchy zoning and porous textures, indicative of an igneous origin (Bouzari et al., 2016). Apatite crystals from the Maoding, Suwalong, and Baimaxueshan intrusions have extremely low sulfur contents, most of which are lower than the analytical detection limit (D.L. = 0.12 wt% SO_3 for the Baimaxueshan and Suwalong intrusions, and 0.04 wt% SO_3 for the Maoding intrusion; Fig. 11; digital App. Table A5).

5. Discussion

5.1. Timing and petrogenesis

Three granitic intrusions from the Jiangda—Weixi Arc belt have yielded ages of 268.3 ± 2.3 Ma, 275.6 ± 1.4 Ma to 264.7 ± 1.4 Ma, and 255.7 ± 1.5 Ma to 249.3 ± 1.1 Ma for the Maoding, Suwalong, and Baimaxueshan granitoids, respectively (Fig. 4). The Suwalong and Baimaxueshan intrusions were emplaced over a time span of ~11 and 6 Myr, respectively, which are consistent with the ~7 to 15 Myr zircon crystallization periods for many porphyry plutons worldwide (Loucks, 2021). Loucks (2021) has further explained such multi-million-year zircon U—Pb age spans within individual plutons by their derivation from long-term and deep-seated differentiation of magmas, probably

also applicable to the Suwalong and Baimaxueshan granitoids. Published age data show that the Tongpu granitoid (Fig. 1) and Jiyidu tonalite (Fig. 2) in the Jiangda—Weixi Arc belt formed at ~263 Ma and ~ 283 Ma (zircon U—Pb dating; Zi et al., 2012b; Wu et al., 2013). In combination with the widespread Early Permian to Early Triassic volcanic rocks and ultramafic–mafic intrusions, a long-lived arc (~40–50 Ma) has been identified, likely related to subduction of the Paleo-Tethyan Ocean (Figs. 1 and 16B; Yang et al., 2014; Xin et al., 2018; Wang et al., 2020; Metcalfe, 2021).

The Maoding, Suwalong, and Baimaxueshan intrusions show similar whole-rock major and trace element compositions, with typical features of subduction derived rocks characterized by high LILE and low HFSE abundances (Figs. 5–6; Pearce, 1996). They are mostly felsic, metaluminous to slightly peraluminous, and calc-alkaline in composition. The geochemistry of the rocks is consistent with partial melting of the mantle wedge, mixed with variable degrees of lower crust-derived melts likely as a result of MASH processes (melting, assimilation, storage, and homogenization) as has been suggested for the generation of continental arc magmas (Audétát and Simon, 2012; Richards, 2003).

The Maoding and Suwalong intrusions have mantle-like Sr—Nd isotopic compositions, typified by relatively low initial Sr isotope ratios and high $\varepsilon_{Nd}(t)$ values [$(^{87}Sr/^{86}Sr)_t = 0.7043–0.7057; \varepsilon_{Nd}(t) = +0.4$ to $+2.8$; Fig. 7]. Zircon crystals from the Maoding intrusion show positive $\varepsilon_{Hf}(t)$ values (14.3 ± 0.6) and mantle-like $\delta^{18}O$ ratios (6.3 ± 0.6 ‰; Fig. 8; Valley et al., 1998), with juvenile single-stage Hf model ages (287 ± 82 Ma). This suggests limited involvement of ancient crustal components in the generation of the Maoding and Suwalong granitoids and is consistent with the positive $\varepsilon_{Nd}(t)$ values. In contrast, the younger Baimaxueshan granitoid shows relatively high $(^{87}Sr/^{86}Sr)_t$ (0.7097–0.7128) and negative $\varepsilon_{Nd}(t)$ (−10.7 to −6.7) values (Fig. 7), consistent with contamination by older crust. Crustal contamination is supported by the presence of numerous xenocrystic and/or inherited zircon grains (digital App. Table A2). Modelling of Sr—Nd isotopic mixing suggests ~30% crustal contamination for the Baimaxueshan but minor (<5%) for the Maoding and Suwalong intrusions with the most likely contaminant being Eastern Qiangtang crust (Peng et al., 2015; Fig. 7). This is also supported by published zircon Hf—O isotope compositions for the Baimaxueshan granitoid which show negative zircon $\varepsilon_{Hf}(t)$ ratios (mostly < −5), higher $\delta^{18}O$ values (mostly >7‰), and older
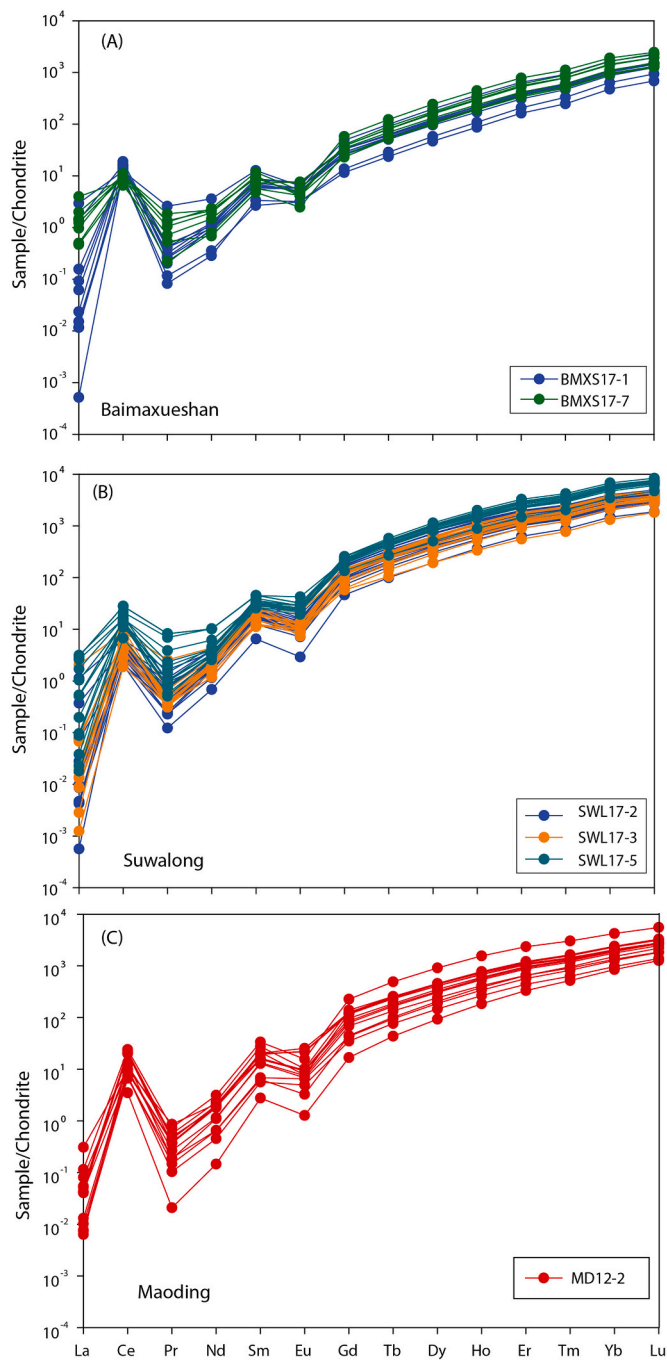

Fig. 10. Plots of zircon Eu_N/Eu_N^* vs. (A) temperatures and (B) ΔFMQ values. Eu_N/Eu_N^* is the europium anomaly, calculated as $Eu_N/Eu_N^* = Eu_N/(Sm_N \times Gd_N)^{0.5}$, using the chondrite normalization values of Sun and McDonough (1989). Temperatures calculated using Ti-in-zircon thermometer by Ferry and Watson (2007): log (ppm Ti-in-zircon) = $(5.711 \pm 0.072) -(4800 \pm 86)/T$ (K) - log a_{SiO2} + log a_{TiO2}, wherein log a_{SiO2} = 1 because of the existence of quartz, and log a_{TiO2} = 0.7 due to the present of the titanite. ΔFMQ values calculated following the method of Loucks et al. (2020). Field for fertile porphyry Cu systems compiled from literature (Dilles et al., 2015; Richards, 2015a; Richards et al., 2017; Tang et al., 2020; Wang et al., 2018b; Zhu et al., 2018). See text for details.

granitoids yielded ΔFMQ values of -0.6 ± 0.5 (n = 17), -3.0 ± 0.6 (n = 54), and -0.8 ± 0.6 (n = 15), respectively, indicative of derivation from reduced magmas (digital Appendix Table A4).

The sulfur content in apatite is controlled by oxygen fugacity, temperature, and the S content in the associated melt (Konecke et al., 2019; Parat et al., 2011; Webster and Piccoli, 2015). The incorporation of sulfur into the apatite structure mainly replaces P and/or Ca as sulfate ions (S^{6+}) in relatively oxidized conditions (Parat et al., 2011; Piccoli and Candela, 2002), although recent studies have shown that apatite crystallized from reduced magmas could contain minor amounts of S, where S occurred as sulfide ions (S^{2-}; Konecke et al., 2019). It is widely accepted that the sulfur species in silicic melts changes from S^{2-} to S^{6+} with increasing magmatic oxygen fugacity (Jugo et al., 2010; Konecke et al., 2019; Tang et al., 2020). Consequently, apatite formed in reduced conditions would have low sulfur contents regardless of the amount of sulfur dissolved in the melt. As most of apatite SO_3 contents in rocks from this study are lower than the analytical detection limit, it is impossible to calculate accurate magmatic fO_2 using apatite S^{6+}/S^{2-} ratios (Konecke et al., 2019; Meng et al., 2021). But the very low sulfur contents in apatite from the three arc granitoids suggest a low magmatic oxygen fugacity (Fig. 11; digital App. Table A5). Taken together, the geochemical compositions of zircon and apatite, suggest that the magmas associated with arc suites in the Jiangda–Weixi belt were reduced.

5.3. Metallogenic implications

The Permian to Early Triassic igneous rocks related to subduction of the Paleo-Tethyan Ocean are widespread in the Jiangda–Weixi Arc belt but host only rare porphyry Cu deposits (Figs. 1 and 2). The scarcity of porphyry deposits in the belt might be explained by uplift of the Tibetan plateau and subsequent exhumation, however, voluminous coeval volcanic rocks in the Jiangda–Weixi belt suggest that erosion alone cannot fully account for the scarcity of porphyry Cu deposits associated in the Sanjiang region (Fig. 1). The generative magmas of the granitic rocks

were generally enriched in water (> 4 wt%), consistent with typical arc and fertile porphyry magmas (Plank et al., 2013; Rezeau and Jagoutz, 2020; Richards, 2015a). However, compared with fertile porphyry systems worldwide (fO_2 = ΔFMQ +1 to +3 with zircon $Eu_N/Eu_N^* > 0.4$ and apatite SO_3 > 0.2 wt%; Dilles et al., 2015; Richards, 2015a; Richards et al., 2017; Wang et al., 2018b; Zhu et al., 2018; Tang et al., 2020), they are relatively reduced (ΔFMQ = -2.1 ± 1.2, n = 101; Fig. 10), which would result in extensive separation of sulfide phases in the melts and loss of chalcophile metals such as Cu (Jugo et al., 2010; Sun et al., 2015). This would limit the fertility for porphyry Cu formation in the Paleo-Tethyan arc belt. Therefore, the magmatic fO_2 rather than water content might play as a critical control on the prospectivity of arc systems.

The Paleo-Tethyan arc in SE Asia is the most productive region for Sn around the world (e.g., Malaysia, Thailand; Romer and Kroner, 2016; Yang et al., 2020). As Sn^{2+} is incompatible in reduced magma and sequestered as Sn^{4+} by Sn-bearing minerals (Lehmann, 2021), reduced magmas can transport Sn and their presence favours the formation of Sn deposits. The presence of Sn deposits therefore is consistent with reduced magmas in the Paleo-Tethyan arc. It is important noting that reduced magmas solely cannot make a magmatic-hydrothermal Sn deposit. Other parameters such as degree of fractionation and nature of the protolith are also of importance for Sn deposit formation (Lehmann, 2021; Zhao et al., 2022).

6. Conclusions

The geochemical compositions and magmatic fertilities of the Permian–Early Triassic igneous rocks in the Sanjiang region, show that the ~275–249 Ma granitoids in the Jiangda–Weixi Arc belt were derived from partial melting of the mantle wedge, that mixed with increased amounts of crust-derived melts over time. Our work shows that the eastern Paleo-Tethyan arc magmas were hydrous but relatively reduced and therefore less fertile for porphyry Cu deposits formation.
Fig. 11. Backscattered electron images of apatite crystals in samples from (A) Baimaxueshan (BMXS17–3), (B) Suwalong (SWL17–5), and (C) Maoding (MD12–1) granitoids. Red circles show the analyzed spots. Concentrations of apatite SO_3 most below the detection limit (D.L. = 0.12 wt% SO_3 for the Baimaxueshan and Suwalong intrusions, and 0.04 wt% SO_3 for the Maoding intrusion).
