Keywords: Jianzhupo deposit LA–ICP–MS Trace element Sphalerite Jamesonite Stibnite

ABSTRACT

The Jianzhupo deposit, the largest Zn-Sb deposit in the Wuxu orefield in China, contains abundant sphalerite and jamesonite, contrasting with typical Sb deposits elsewhere. Whether the Sb and Zn in the deposit derived from similar parental sources is not clearly resolved. Here, trace-element compositions of sulfides from the deposit were determined by laser ablation–inductively coupled plasma–mass spectrometry (LA-ICP-MS). Results indicate that jamesonite is an important Cd-bearing sulfide with Cd contents of 523–764 ppm and minor or no significant Cd variations were observed within jamesonite crystals. Trace-element compositions of jamesonite indicates that Cd enters the lattice by coupled substitution as $2Fe^{2+} \leftrightarrow 2n^{2+} + Cd^{2+}$. Due to similar geochemical behaviors between Zn and Cd in hydrothermal systems, Zn/Cd ratio of sphalerite was suggested as a robust geochemical tracer to distinguish metal sources in such systems. Here, we summarized the Zn/Cd ratios of sphalerite from various hydrothermal systems and the results show that values between 169 and 233, and lower than 44 are from high- and low-temperature temperature fluid conditions, respectively. Due to different Zn/Cd ratios between sediments and igneous rocks, we conclude that metals in sphalerite from the Jianzhupo deposit were likely derived from granite; in contrast, metals in jamesonite were related to sedimentary rocks. These conclusions are consistent with previous studies on the deposit. Overall, our results indicate that ore-forming fluids of the Jianzhupo deposit were derived from magmatic–hydrothermal and basin water. This study extends the application of trace-element compositions in resolving the sources of sulfides in hydrothermal systems.

1. Introduction

The Jianzhupo deposit is located in the Wuxu orefield in Guangxi Province, China, in the southeastern Danchi metallogenic belt, which is well known as a non-ferrous metal production area with several largescale deposits such as the Dachang Zn–Sn–Sb–In deposit [\(Fig. 1;](#page-1-0) [Cai](#page-10-0) [et al., 2012; Liu et al., 2015\)](#page-10-0). Pb–Zn–Sb polymetallic deposits are concentrated in the middle of the Wuxu orefield, while those in the north and southeast are mainly Hg deposits formed under low-temperature conditions ([Fig. 1C](#page-1-0)).

Due to the lack of exposed granite in the study area, the genesis of ore deposits in the Wuxu orefield is not well constrained. Thus, tracing their metal sources and analyzing metal combinations would improve our understanding of metallic mineralization and guide anamineral exploration. As the largest deposit in the Wuxu field, the Jianzhupo deposit has been studied in terms of S isotopes, bulk trace element compositions of sphalerite, H–O isotopes, and fluid inclusions [\(Zhang et al., 2018a, b;](#page-11-0) [Liu et al., 2020](#page-11-0)), but the source of ore-forming fluids is debated. Based on S isotopes and trace elements in sphalerite, the fluids may be mainly of magmatic–hydrothermal origin ([Liu et al., 2020; Xiao, 2022\)](#page-10-0); however, H–O isotopic compositions of fluid inclusions indicate an origin from both magmatic–hydrothermal and basin waters (Zhang et al., 2018 a, b). Recently, Cd isotope signatures of sphalerite and jamesonite are different, and the results also support that metals from the deposit were

derived from mixture of igneous and sedimentary rocks ([Yang et al.,](#page-11-0) [2023\)](#page-11-0).

LA–ICP–MS is useful in determining the geochemical compositions of minerals formed in various types of hydrothermal systems, and has been widely applied in analyzing sulfides to trace mineralization conditions and deposit genesis, and in the classification of hydrothermal systems ([Cook et al., 2009; Ye et al., 2011; Wei et al., 2018; Li et al., 2019a,](#page-10-0) [2019b; Hu et al., 2020; Li et al., 2021; Liu et al., 2022](#page-10-0)). For example, sphalerite from different types of deposit has characteristic patterns of trace-element enrichment: Mississippi Valley type (MVT) deposits are enriched in Ge, Cd, and Ga; epithermal deposits in As, Ag, Sb, and Mo; skarn deposits in Mo and Co; and volcanogenic massive sulfide (VMS) and sedimentary exhalative (SEDEX) deposits in Mn, Fe, and In ([Cook](#page-10-0) [et al., 2009; Li et al., 2020](#page-10-0)). Deposit types have also been classified by comparison of binary plots of trace elements in sulfides ([Ye et al., 2011;](#page-11-0) [Hu et al., 2021\)](#page-11-0). By comparing the trace element composition of stibnite from different types of Sb deposits, the deposit type can be effectively determined (Fu et al., 2020; [Song et al., 2022; Zhou et al., 2023](#page-11-0)). Such as, Fu et al. (2020) found that the Hg / (Cu + Pb) ratio of the Xikuangshan deposit is greater than 1 and metals from this deposit are dominantly derived from basements; in contrast, the Woxi deposit is lower than 1 and basements were not likely provided metals to the deposit. Such studies have established that geochemical compositions of sulfides may record information on ore-forming processes in Sb deposits.

Here, LA–ICP–MS was applied in determining the major- and traceelement compositions of sphalerite, jamesonite, and stibnite in the Jianzhupo deposit. Based on the correlations between elemental concentrations, we investigated enrichment mechanisms of major and trace elements, and discuss metal sources of the deposit by comparing various

elemental enrichment signatures in different types of hydrothermal systems.

2. Geological setting

2.1. Regional geology

The Wuxu, Mangchang, and Dachang orefields form the main framework of the Danchi metallogenic belt (Fig. 1B; [Xiao, 2018](#page-11-0)), lying on the outer southwestern margin of the Jiangnan Massif and the northeastern margin of the Youjiang Basin (Fig. 1B) at the intersection of the Paleo-Tethyan and Paleo-Pacific tectonic domains [\(Zhao and Liu,](#page-11-0) [2016; Xu et al., 2019\)](#page-11-0). Geological events provided favorable conditions for the formation of Pb–Zn–Sb deposits (Fig. 1A, B; [Fu et al., 1993; Cai](#page-10-0) [et al., 2007; Xiao et al., 2022a\)](#page-10-0). Devonian, Carboniferous, Permian, and Triassic strata are exposed in the Wuxu orefield (Fig. 1C). Devonian strata contain the main host rocks of polymetallic deposits, mainly mudstone, marlstone, siliceous rocks, and limestone [\(Zhang et al.,](#page-11-0) [2018a,](#page-11-0) b). Carboniferous strata comprise mainly mudstone, limestone, and dolomite; Permian strata limestone, marlstone, and siliceous rock; and Triassic strata mudstone, shale, limestone, siltstone, and siliceous rock [\(Zhang et al., 2018a, b; Xiao, 2018](#page-11-0)).

NNW-trending folds and transtensional faults constitute the main structural framework of the Wuxu orefield. E–W-trending faults were formed through torsion of the NNW-trending faults, which cut secondstage NNE-trending faults that formed during late tectonic activity (Fig. 1C; [Liu et al., 2020; Xiao, 2018](#page-10-0)). Magmatic rocks are exposed in the Mangchang and Dachang orefields, but not in the Wuxu orefield (Fig. 1B; [Liang et al., 2011; Zhao et al., 2018\)](#page-10-0). Negative gravity

Fig. 1. (A) Tectonic sketch map; (B) Geological sketch map of the Danchi polymetallic ore belt (after [Cai et al., 2012\)](#page-10-0); (C) Geological map of the Wuxu ore field (after [Cai et al., 1995](#page-10-0)). Granites in Dachang mainly consist of biotite granites (the Longxianggai pluton) and granite/diorite porphyry dykes [\(Guo et al., 2018](#page-10-0)); Magmatic rocks exposed in Mangchang are grain granites and porphyritic granites, and their related granite dykes [\(Wu et al., 2020\)](#page-11-0).

anomalies indicate that unexplored granite is likely existed in the middle of the Wuxu orefield ([Fig. 1](#page-1-0)C; [Sun et al., 1994](#page-11-0)).

2.2. Deposit geology

The Jianzhupo deposit is the largest Pb–Zn–Sb polymetallic deposit in the Wuxu orefield ([Zhang et al., 2018a, b; Xiao, 2022\)](#page-11-0). The main exposed strata in the field are from the Tangding Formation, which is subdivided into three units based on lithology: Unit 1 comprises mainly mudstone and siltstone; Unit 2 mudstone, marlstone, and silty mudstone; and Unit 3 mudstone and silty mudstone ([Chang et al., 2016;](#page-10-0) [Xiao et al., 2022a](#page-10-0), b). Faults in the mining area are predominantly NNWtrending transtensional faults and NNE-trending torsional faults. The former are consistent with the trend of orebodies and are the main orecontrolling structures (Fig. 2A; [Xiao, 2018](#page-11-0)).

In Unit 2, orebodies trend NNW and occur mainly in vein, strip, and lenticular forms, with their size and shape controlled mainly by NNWtrending faults (Fig. 2 A, B; [Hu et al., 2017; Xiao, 2018\)](#page-10-0). More than 130 veins have been identified in the Jianzhupo deposit, with the main veins being J1, J3, J6, J7, J9, J10, J13, J30, J33, and J59, which

together contain large metal reserves ([Zhao and Liu, 2016](#page-11-0)). The economic minerals are predominantly sphalerite and jamesonite with minor pyrite, stibnite and galena, together accounting for *>* 90% of the total economic minerals. Gangue minerals include quartz, calcite, and sericite ([Zhang et al., 2018a](#page-11-0), b). Based on field observations, the ores can be divided into two types, including the massive and veined ores ([Yang](#page-11-0) [et al., 2023](#page-11-0)). As the two predominant economic minerals in the deposit, sphalerite is closely associated with jamesonite, and sphalerite is commonly crossed by needle-like jamesonite. Sphalerite has colors varying from black to light, and is mainly subhedral to anhedral. ([Fig. 6A](#page-6-0)). Jamesonite is present as needle-like or spotted crystals in sphalerite ([Fig. 3A](#page-3-0), B).

Field and optical microscopy observations [\(Fig. 3\)](#page-3-0) indicate three metallogenic stages: (I) a quartz–pyrite stage that produced mainly pyrite; (II) a quartz–cassiterite sulfide stage that produced large amounts of sphalerite, jamesonite, galena, and stibnite; and (III) a quartz–carbonate stibnite stage that produced mainly carbonate minerals and minor stibnite [\(Liu et al., 2020; Xiao et al., 2021](#page-10-0)).

Fig. 2. Geological sketch map (A; modified from [Wang, 2012](#page-11-0)) and cross-section along the No. 300 exploration line (B; modified from [Cai et al., 1995\)](#page-10-0) of the Jiangzhupo deposit.

3. Sampling and analysis

Samples were collected from different mining levels in the Jianzhupo deposit, with representative examples being made into polished thin sections. Major- and trace-element compositions of sphalerite, jamesonite, and stibnite were determined by LA–ICP–MS at the Institute of Geochemistry, Chinese Academy of Sciences, Guangxi Province, China, using Agilent 7700x ICP–MS (Agilent technologies, USA) and New Wave UP213 LA (New Wave Research, UK) systems. Instrument settings were as described by [Wei et al. \(2021\).](#page-11-0) Standards GSE-1G and GSD-1G were used as external standards in quantitative calibration, and results were corrected using the sulfide standard MASS-1 ([Wei et al., 2021; Zhou](#page-11-0) [et al., 2022](#page-11-0)). Uncertainties for most elements were *<* 10%, based on comparison with reference values. Concentrations of the following were determined: 23 Na, 25 Mg, 27 Al, 29 Si, 45 Sc, 49 Ti, 51 V, 53 Cr, 55 Mn, 57 Fe, 59 Co, 60 Ni, 65 Cu, 66 Zn, 71 Ga, 72 Ge, 74 Ge, 75 As, 77 Se, 90 Zr, 93 Nb,

4. Results

A total of 76 LA points were used for trace-element analysis: 40 in sphalerite, 29 in jamesonite, and 7 in stibnite. Major- and trace-element compositions are listed in [Electronic Appendix Table S1, 2, 3](#page-1-0).

The sphalerite samples are enriched in Mn, Fe, Cu, Cd, and Sn, with mean contents of 923, 38,630, 2,811, 7,473, and 3,703 ppm, respectively. Jamesonite is enriched in Mn, Cu, Zn, As, Ag, Cd, and Sn, with mean contents of 1,381, 1,569, 490, 217, 596, 649, and 350 ppm,

respectively. Stibnite is enriched in Cu, Zn, As, and Pb, with mean contents of 212, 434, 296, and 909 ppm, respectively.

5. Discussion

5.1. Trace-element substitution mechanisms in sphalerite

Trace elements in sphalerite occur mainly in solid solution, as nanoparticles, or as mineral micro-inclusions ([Cook et al., 2009; Li et al.,](#page-10-0) [2020; Hu et al., 2021; Liu et al., 2022\)](#page-10-0). The occurrence forms of trace elements can effectively be judged by LA–ICP–MS signal fluctuations in time-resolved depth profiles. A 'flat' signal profile commonly indicates a solid solution or evenly distributed nanoparticles (Ye et al., 2011; [Gregory et al., 2014; Hu et al., 2020\)](#page-11-0), while strong signal fluctuations indicate mineral micro-inclusions or an uneven distributions of nanoparticles [\(Cook et al., 2009; Ye et al., 2011; Ye et al., 2016; Zhuang et al.,](#page-10-0) [2019\)](#page-10-0).

Signals for Zn, Fe, Mn, Sn, Cu, and Cd were flat [\(Fig. 4A](#page-4-0), B), indicating that these elements are present as solid solution or evenly distributed nanoparticles. Signals of In, Ag, Ga, Pb, Sb displayed little fluctuation [\(Fig. 4](#page-4-0)C, D), implying solid-solution, nanoparticles, and micro-inclusions. As signal fluctuated strongly [\(Fig. 4D](#page-4-0)), indicating its occurrence in micro-inclusions or non-uniform nanoparticles.

In the sphalerite, Zn and Fe contents are negatively correlated ([Fig. 5](#page-5-0)A), implying that Fe may directly substitute for Zn. The Mn content is negatively correlated with Fe and Cd contents ([Fig. 5](#page-5-0)B, C), implying that Mn inhibits Fe and Cd substitution. The Fe^{2+} , Mn²⁺, and Cd²⁺ have similar ionic radii of 0.63, 0.66, and 0.78 \times 10⁻¹⁰ m,

 \circledR

60

60

 (D)

Fig. 4. Representative LA-ICP-MS time-resolved depth profiles for sphalerite.

respectively. So, these elements may directly substitute for Zn in the sphalerite lattice (Zn \leftrightarrow Fe, Cd, Mn) (Cook et al., 2009; Ye et al., 2011; [Belissont et al., 2014, 2016; Hu et al., 2021; Liu et al., 2022\)](#page-10-0). Due to their relatively low contents, Cd and Mn show no significant negatively correlation with Zn [\(Fig. 5](#page-5-0)D–F).

The charges and ionic radii of Cu, Pb, Sb, As, Ag, and Sn may differ from those of Zn, and these elements commonly occur as coupled substitutes in sphalerite ([Cook et al., 2009, 2012; Ye et al., 2011; Makovicky](#page-10-0) [and Topa, 2015](#page-10-0)). Cu, Sn, and Ga contents are positively correlated ([Fig. 5](#page-5-0)G–I), suggesting likely substitution mechanisms of $4\text{Zn}^{2+} \leftrightarrow 2\text{Cu}^+$ $+$ Ga³⁺ + Sn³⁺ or 2Zn²⁺ \leftrightarrow Cu⁺ + Ga³⁺ (Zhuang et al., 2019; Liu et al., [2022\)](#page-11-0). Sn is strongly correlated with Cu and Ag ([Fig. 5G](#page-5-0), J), with a possible substitution mechanism of $2\text{Zn}^{2+} \leftrightarrow \text{Sn}^{3+} + (\text{Cu}^+, \text{Ag}^+)$ (Cook [et al., 2009](#page-10-0)). Thus, the possible substitution mechanisms are $2\text{Zn}^{2+} \leftrightarrow$ $Ag^+ + Ga^{3+}$ and $2\text{Zn}^{2+} \leftrightarrow 2\text{Ag}^+ + \text{Cu}^{2+} + \square$ (vacancy) [\(Fig. 5](#page-5-0)K, L). The As content is positively correlated with Pb and Sb contents [\(Fig. 5](#page-5-0)M, N,). Based on the possible substitution mechanisms suggested by [Zhuang](#page-11-0) [et al. \(2019\)](#page-11-0) and Makovicky et al. (2015), we conclude that As substitution may occur through $4Zn^{2+} \leftrightarrow Pb^{2+} + 2As^{3+} + \Box$ and $3Zn^{2+} \leftrightarrow Sb^{3+}$ $+ As^{3+}$ + \Box . There is a strong positive correlation between Pb and Sb ([Fig. 5](#page-5-0)O), with similar signal profiles (Fig. 4D). Sphalerite Pb and Sb contents vary greatly, with respective ranges of 0–16,411 and 1–7705 ppm. Thus, Pb and Sb in sphalerite may occur as jamesonite microinclusions [\(Fig. 3](#page-3-0)A, B).

5.2. Distribution of trace elements in sphalerite color zones

Sphalerite color is likely controlled mainly by Fe content, with dark

sphalerite commonly having higher Fe contents than pale sphalerite ([Belissont et al., 2014; Wen et al., 2019; Hu et al., 2020; Wei et al.,](#page-10-0) [2021\)](#page-10-0). The LA–ICP–MS analyses indicate that Fe has the highest concentration of all trace elements in sphalerite ([Table 1\)](#page-6-0), and Fe increases from pale color to brown zones, with median values for pale, paleyellow, and brown zones of 23,124, 28,022, and 34,256 ppm, whereas the median Zn contents decrease (633,558, 628,329, and 604,905 ppm, respectively; [Fig. 6A](#page-6-0), B). Zn and Fe contents have a strong negative correlation ([Fig. 6B](#page-6-0)). Trends in Sn, Cu, Sb, Ga, and Ag contents are similar to that of Fe (Fig. $6A$, D), and concentrations of these elements increase from dark to pale sphalerite. with mean values for pale, paleyellow, and brown zones respectively as follows: Sn, 109, 276, and 10,092 ppm; Cu, 101, 265, and 7,667 ppm; Sb, 16, 29, and 228 ppm; Ga, 3.05, 3.40, and 12.77 ppm; and Ag, 2.40, 3.82, and 31.32 ppm ([Table 1](#page-6-0)). There is no obvious correlation of Cd, Mn, As, In, or Pb contents with sphalerite color ([Fig. 6A](#page-6-0), C). Although variations of Sn, Cu, Sb, Ga, and Ag contents between sphalerite color zones are similar to that of Fe content, Fe is likely the dominant factor controlling sphalerite color due to its relatively high content.

5.3. Trace elements in jamesonite and stibnite

In jamesonite, signal profiles for Mn, Cu, Zn, As, Ag, Cd, Sn, and In are relatively flat in the time-resolved depth profiles [\(Fig. 7A](#page-7-0)–D), indicating that these elements occur mainly in solid-solution form or as evenly distributed nanoparticles [\(Ye et al., 2011; Gregory et al., 2014;](#page-11-0) [Hu et al., 2020\)](#page-11-0), while the profile for Tl show little fluctuation, implying solid-solution, nanoparticle, and micro-inclusion forms (Cook et al.,

	S.D.	52	1885	1050	3389	1.99	0.60	27	1.68	992	46	0.21	0.36

[2009; Ye et al., 2011; Ye et al., 2016; Zhuang et al., 2019\)](#page-10-0). In stibnite, Cu, Pb, and As similarly occur mainly in solid-solution or evenly distributed nanoparticle forms; Zn and Ag in solid-solution, nanoparticle, and micro-inclusion forms; and Cd, Sn, and Tl, which have strongly fluctuating signal profiles that may be caused by their low concentrations. ([Fig. 7](#page-7-0)E, F ([Cook et al., 2009; Ye et al., 2011; Ye et al.,](#page-10-0) [2016; Zhuang et al., 2019](#page-10-0)).

Bivalent Mn, Fe, Cd ions have radii similar to that of Zn^{2+} and are able to directly replace Zn in the sphalerite lattice [\(Cook et al., 2009; Ye](#page-10-0) [et al., 2011; Zhuang et al., 2019; Hu et al., 2021; Liu et al., 2022; Zhou](#page-10-0) [et al., 2022](#page-10-0)). Furthermore, Zn content is positively correlated with Mn and Cd contents, suggesting that Mn, Cd, and Zn may replace Fe in the jamesonite lattice according to $2Fe^{2+} \leftrightarrow Zn^{2+} + Cd^{2+}$ or $2Fe^{2+} \leftrightarrow Zn^{2+} +$ Mn^{2+} ([Fig. 8](#page-8-0)A, B). In stibnite, the strong positive correlation of Pb content with Cu and As contents and their flat time-resolved depth profiles ([Fig. 7E](#page-7-0), F and 8C, D) indicate that these elements enter stibnite through coupled substitution mechanisms of $Cu^+ + Pb^{2+} \leftrightarrow Sb^{3+} + \Box$ and/or $3Pb^{2+}+As^{3+} \leftrightarrow 3Sb^{3+}+\Box$.

5.4. Substitution of Cd in jamesonite

Cd and Zn are in the same group in the periodic table and therefore have similar chemical properties, with Cd usually occurring in sphalerite through isomorphic replacement of Zn [\(Tu et al., 2004; Cook et al.,](#page-11-0) [2009\)](#page-11-0). In the present study, measured sphalerite Zn and Cd contents are \sim 620,960 and \sim 7707 ppm, respectively, with a mean Zn/Cd ratio of 83. Zn and Cd contents of jamesonite were relatively stable, with means of 490 and 649 ppm, respectively, and a mean Zn/Cd ratio of 0.76, much

Fig. 7. Representative LA-ICP-MS time-resolved depth profiles for jamesonite (A to D) and stibnite (E, F).

Fig. 8. Correlation plots of jamesonite (A, B) and stibnite (C, D): (A) Mn vs. Zn, (B) Zn vs. Cd, (C) Cu vs. Pb, (D) As vs. Pb.

lower than that of sphalerite. Jamesonite Zn, Cd, and Fe contents are stable from crystal margin to core (Fig. 9), implying that these elements are not affected by surrounding sphalerite. Cd in jamesonite is thus not derived from sphalerite micro-inclusions; rather, its flat time-resolved depth profiles [\(Fig. 7](#page-7-0)C) suggest that Cd replaces an ion in the jamesonite lattice.

The chemical formula of jamesonite is $Pb_4FeSb_6S_{14}$, comprising $\text{Pb}^{2+}, \text{Fe}^{2+}, \text{Sb}^{3+},$ and $\text{S}^{2-}.$ The valence states of Fe and Pb are the same as the common Cd^{2+} state, so Cd is more likely to replace these ions. The coordination number of Sb^{3+} in both jamesonite and stibnite is three, but the latter contains no Cd, precluding replacement of Sb by Cd in jamesonite [\(Table S3](#page-1-0); [Zhao et al., 2015](#page-11-0)). In the jamesonite crystal lattice, the coordination number of Pb is six. The Pb valence state in galena $is + 2$ and its coordination number six, as for jamesonite, but galena contains no Cd, so it is unlikely that Cd replaces Pb in jamesonite [\(Zhao](#page-11-0) [et al., 2015](#page-11-0)). In jamesonite, the coordination number of Fe is four while in pyrite it is six, and pyrite contains no Cd [\(Wang et al., 2019\)](#page-11-0). With a coordination number of four, the ionic radii of $\text{Zn}^{\Sigma+}$, Cd^{2+} , and Fe^{2+} are

Fig. 9. Image and trace element concentrations of jamesonite.

similar at 0.6, 0.78, and 0.63 \times 10⁻¹⁰ m, respectively, so they may substitute for each other ([Zhou et al., 2012](#page-11-0)). It has been shown previously that Cd and Fe directly replace Zn in the sphalerite lattice ([Cook](#page-10-0) [et al., 2009; Ye et al., 2011; Hu et al., 2021; Liu et al., 2022; Belissont](#page-10-0) [et al., 2014](#page-10-0), 2016) and, similarly, Cd and Zn may replace Fe in jamesonite. The Cd content has a strong positive correlation with Zn content in the jamesonite [\(Fig. 8B](#page-8-0)), so we speculate that Cd and Zn occur in jamesonite through a coupled substitution mechanism of $2Fe^{2+} \leftrightarrow Zn^{2+}$ $+ Cd^{2+}$, but this requires further verification.

5.5. Implications

The mineralization environment and metal sources of sphalerite may be elucidated through analysis of its trace-element composition ([Cook](#page-10-0) [et al., 2009; Ye et al., 2011; Belissont et al., 2014; Hu et al., 2020; Li](#page-10-0) [et al., 2020; Liu et al., 2022\)](#page-10-0). For example, magmatic deposits have relatively high contents of Fe, In, and Mn [\(Ye et al., 2011; Murakami and](#page-11-0) [Ishihara, 2013; Wei et al., 2018; Liu et al., 2022](#page-11-0)), while lowertemperature deposits are enriched in As, Cd, Ge, Tl, Ga, and Se ([Cook](#page-10-0) [et al., 2009; Ye et al., 2011; Yuan et al., 2018; Zhuang et al., 2019](#page-10-0)). Sphalerite of the Jianzhupo deposit is enriched in Mn, Fe, Cu, Cd, and Sn; depleted in Ga, As, Ag, and In; and free of Ge, Tl, and Se. Its traceelement composition is similar to that of magmatic deposits, and its ore-forming fluids may be magmatic–hydrothermal.

Distributions of trace elements in different deposits are summarized in binary plots in Fig. 10. Mineralization conditions of a deposit can be determined through comparison with typical deposits ([Ye et al., 2011; Li](#page-11-0) [et al., 2020; Liu et al., 2020; Hu et al., 2021\)](#page-11-0). Here, most sphalerite samples plot in the VMS and Skarn deposit fields (Fig. 10), so the Jianzhupo deposit is likely of magmatic–hydrothermal origin.

Cd and Zn have similar geochemical properties and follow similar geological evolutions, especially when combined with S [\(Tu et al., 2004;](#page-11-0) [Metz and Trefry, 2000\)](#page-11-0). The sources of ore-forming fluids have been intensively studied through comparison of mineral Zn/Cd ratios (e.g., [Wen et al., 2016; Metz and Trefry, 2000\)](#page-11-0). In most previous studies, Cd contents were generally high in sphalerite and very low in other minerals, so they were limited to analyses of Zn/Cd ratios in sphalerite ([Wang et al., 2016](#page-11-0)). However, jamesonite in the Jianzhupo deposit has high Cd contents, allowing elucidation of the genesis of the deposit through comparison of Zn/Cd ratios of sphalerite and jamesonite. Cd is generally enriched in low-temperature sedimentary deposits, and Zn/Cd ratios in sphalerite are high in high-temperature deposits such as the Baiyinnuoer and the Gacun deposits (mean $Zn/Cd = 226$ and 193, respectively), while for low-temperature deposits such as the Fule and

the Dadongla deposits the mean ratios are lower at 33 and 30, respectively [\(Wen et al., 2016](#page-11-0)). In the present study, Zn/Cd ratios of sphalerite in the Jianzhupo deposit range from 64 to 105 (mean 83), similar to the Dongpo orefield (59–116, mean 83) (Fig. 11A; [Li and Peng, 1989\)](#page-10-0). The Dongpo orefield has a medium-temperature hydrothermal type source, with ore-forming fluids derived mainly from igneous rocks and sediments ([Liu, 2003](#page-10-0)). The Zn/Cd ratios reported for the Jianzhupo orefield are slightly lower than those of the Mangchang (110–115, mean 112) and Dachang (108–159, mean 130) orefields (Fig. 11A; [Wei et al., 2017;](#page-11-0) [Tang, 2017](#page-11-0)). Both these orefields include magmatic-rock exposures, with ore-forming fluids are closely related to magmatic–hydrothermal ([Wang et al., 2004; Pi et al., 2015; Tang, 2017\)](#page-11-0). We speculate that the slightly lower Zn/Cd ratios of sphalerite in the Jianzhupo deposit may be caused by magmatic–hydrothermal fluids mixing with basin water during mineralization. [Yang et al. \(2023\)](#page-11-0) conducted Cd isotopic analysis of sulfides in the Jianzhupo deposit, and the results showed that the metals of sphalerite and jamesonite were derived from igneous rocks and sedimentary rocks, respectively.

The Zn/Cd ratios of jamesonite in the Jianzhupo deposit range from

Fig. 11. Zn/Cd ratios from different types of deposits. (A) Zn/Cd ratios of sphalerite, (B) Zn/Cd ratios of jamesonite. These data are collected from [Wen](#page-11-0) [et al. \(2016\), Wang et al. \(2016\), Tang \(2017\), Wei et al. \(2017\)](#page-11-0) and Li (2019c).

Fig. 10. Binary plots of (A) Fe vs. Mn, (B) Mn vs. Cd/Fe in sphalerite. These data are collected from [Cook et al. \(2009\), Ye et al. \(2011](#page-10-0), 2016), George et al. (2015, [2016\)](#page-10-0), [Li et al. \(2020\)](#page-10-0) and [Liu et al. \(2022\)](#page-10-0).

0.67 to 0.89 (mean 0.76), notably lower than values for the Gutaishan deposit, which is characterized by magmatic–hydrothermal ore-forming fluids ([Fig. 11B](#page-9-0); Li, 2019c). This may reflect a decrease in the proportion of magmatic–hydrothermal fluids during mineralization of part of the orebody with an increasing predominance of metal fluids from basin water, resulting in the formation of a high-grade jamesonite orebody in some ore sections. We conclude that ore-forming fluids of the Jianzhupo deposit are of magmatic–hydrothermal and basin-water origin.

6. Conclusions

- (1) Fe, Mn, and Cd can directly substitute for Zn in sphalerite lattice $(Zn \leftrightarrow Fe, Cd, Mn)$. Cu, Pb, Sb, As, Ag, and Sn exist in sphalerite by coupled substitution mechanisms, and the substitution mechanisms include: $4Zn^{2+} \leftrightarrow 2Cu^{+} + Ga^{3+} + Sn^{3+}$, $2Zn^{2+} \leftrightarrow Cu^{+} +$ Ga^{3+} , $2Zn^{2+} \leftrightarrow Sn^{3+} + (Cu^+, Ag^+), 2Zn^{2+} \leftrightarrow Ag^+ + Ga^{3+}, 2Zn^{2+}$ $\leftrightarrow 2\text{Ag}^+ + \text{Cu}^{2+} + \square$, $4\text{Zn}^{2+} + \text{Pb}^{2+} + 2\text{As}^{3+} + \square$ and $3\text{Zn}^{2+} \leftrightarrow$ $Sb^{3+} + As^{3+} + \Box$ (vacancy). Mn, Cd, and Zn may replace Fe in the jamesonite as $2Fe^{2+} \leftrightarrow Zn^{2+} + Cd^{2+}$ or $2Fe^{2+} \leftrightarrow Zn^{2+} + Mn^{2+}$. The coupled substitution mechanisms of Cu, Pb and As in stibnite are $Cu^++Pb^{2+} \leftrightarrow Sb^{3+}+\square$ and/or $3Pb^{2+}+As^{3+} \leftrightarrow 3Sb^{3+}+\square$.
- (2) In binary composition plots, most sphalerite samples plot in the VMS and Skarn deposit fields, indicating that ore-forming fluids may be of magmatic–hydrothermal origin, although Zn/Cd ratios of sphalerite and jamesonite indicate two types of ore-forming fluid in the Jianzhupo deposit: magmatic–hydrothermal and basin-water fluid.
